Esophageal perforation during an ACDF is potentially disastrous complication.⁷⁹ The perforation can be identified intraoperatively by filling the esophagus with indigo carmine via a nasogastric tube while blocking the esophagus distal to the tube with a finger before wound closure or by performing intraoperative endoscopic esophagoscopy. After surgery, the presence of subcutaneous emphysema on X-rays or CT scan might be indicative of esophageal perforation, and the patient needs to be further examined and appropriately treated.⁷⁴ Vertebral artery injury can occur from excessive lateral dissections or from an abnormal course of the vertebral artery. The width of the corpectomy should be carefully planned before surgery using the preoperative CT images to avoid the vertebral artery. The uncovertebral joint is a reliable anatomical landmark for the lateral border of the vertebral body. In most cases, there is sufficient collateral flow to avoid severe permanent neurological deficit, but transient deficits can be seen in 50% of patients. In cases with dominant vertebral artery injury, permanent neurologic injury can occur.⁸⁰ If a vertebral artery injury is identified, pressure is applied with hemostatic agents and a cottonoid patty for several minutes. During this time, it is useful to call an assistant into the room as well as inform interventional radiology of the injury. Most often, the injury is a partial injury and has the potential to stop through vasoconstriction. If it does not stop, the vertebral artery can be ligated or repaired. The

artery is exposed by following the uncinat process out laterally over the transverse process; the bone overlying the artery is then resected with a small Kerrison. An angiogram is performed postoperatively to ensure that there is not a vertebral artery dissection that needs to be embolized.

KEY POINTS

- Most patients with CSM have a stepwise progression in their neurological dysfunction after the onset of symptoms. Surgery can alter the natural history and change the prognosis of patients with CSM.
- The choice of either an anterior or a posterior procedure for decompression of CSM is based on multiple factors, such as the location of the compressive pathology, the extent of the degenerative process, and the sagittal alignment of the cervical spine.
- An alternate method to improve the fusion rate after multilevel decompression is corpectomy. Corpectomy provides a more extensive decompression. Hybrid procedures of ACDF and corpectomy can also be applied for multilevel disease.
- Various graft materials were reported for use in the anterior procedure, such as autograft, allograft, titanium cage, PEEK cage, PMMA, and hydroxyapatite.
- Complications related to the anterior surgical procedure include recurrent laryngeal nerve injury, dysphasia, C5 palsy, hematoma, esophageal perforation, and vertebral artery injury.

INTRODUCTION

The causes of cervical spondylotic myelopathy (CSM) include compression at single or multiple levels, cervical malalignment, instability, or congenital stenosis. The decision of using an anterior or posterior surgical approach is often controversial and is based on the number of segments involved, location of compression (anterior vs. posterior), and radiographic sagittal alignment.

Any posteriorly based procedure relies on the ability of the spinal cord to float away from the spine after it is decompressed. In the presence of a kyphotic spine, despite taking pressure off posteriorly, the cord can potentially remain draped over the anterior disk osteophyte complexes leading to inadequate decompression of the cord. A posteriorly based procedure is ideally performed in patients with adequate lordosis. It is critical to assess cervical lordosis, cervical sagittal balance, as well as the location of the compressive elements through the posterior spinal line (PSL) when choosing a posterior based procedure.^{1,2} Cervical alignment has traditionally been measured with a C2-C7 Cobb's angle. It is our preference to use the method described by Toyama et al. that involves drawing a line from the posterior inferior corner of C2-C7 and examining its relationship to the posterior vertebral bodies. If the line is posterior to the posterior vertebral bodies, then the overall alignment of the spine is lordotic.^{3,4} If the line is at the same level as the posterior bodies, then the cervical spine is neutral. If the line is anterior to the

Fig. 43.1: Assessing cervical lordosis as defined by Toyama by drawing a line from the posterior corner of C2 to the posterior superior corner of C7. The alignment is neutral to slightly lordotic as the line is just posterior to the posterior vertebral bodies. Cobb angle in red.

vertebral bodies, then the alignment is kyphotic (Fig. 43.1). Although a magnetic resonance imaging (MRI) is useful for determining the location and severity of spinal cord compression, it should not be used to assess cervical alignment. Occasionally, a lateral radiograph can demonstrate well-maintained lordosis, while the sagittal MRI shows a neutral or kyphotic spine. Conversely, a lateral radiograph may show lack of normal lordosis, while the supine MRI shows that the patient has the ability to achieve lordosis (Figs. 43.2A and B). These differences are most likely

Figs. 43.2A and B: (A) Lateral radiograph demonstrating lordosis with a sagittal MRI of the same patient demonstrating kyphosis. (B) Lateral radiograph demonstrating loss of lordosis and straightening of the cervical spine with a sagittal MRI of the same patient demonstrating lordosis.

attributable to the fact that the patient is supine during the MRI. It is our preference to measure cervical alignment on a standing upright lateral radiograph when determining if a patient has enough lordosis to undergo a posterior procedure. A lateral extension radiograph is also critical as the patient's ability to achieve lordosis on extension gives the surgeon further information on the ability to achieve appropriate alignment during surgery in the setting of a fusion. In patients who have too much pain to actively extend, a cross table lateral radiograph with the patient passively extended can be useful when a bump is placed under the periscapular region.

Cervical lordosis is related to both overall and cervical sagittal balance. Overall sagittal balance dictates that a vertical line drawn from the C7 body on a 36 inch full length lateral radiograph should coincide with the posterior superior corner of the L5-S1 disk space.⁵⁻⁸ Both increased thoracic kyphosis and decreased lumbar lordosis in aging patients leads to compensatory lordosis of the cervical spine in order for the patient to maintain horizontal gaze.^{9,10} Once overall positive sagittal balance is corrected by operating on the lumbar spine, there is improvement of the abnormal cervical hyperlordosis through reciprocal changes.¹¹ Cervical lordosis should be evaluated with the knowledge that it is affected by overall sagittal balance. Cervical sagittal balance is measured by the C2-C7 cervical sagittal vertical axis (C2-C7 SVA), which is the distance from the C2 plumb line to the posterior superior corner of the C7 vertebral body.¹² The outcome of posteriorly based cervical spine surgery has been shown

Fig. 43.3: Cervical sagittal balance measured by the C2-C7 SVA in red (distance of the C2 plumb line in green to the posterior superior corner of C7).

to be related to preoperative cervical sagittal balance.¹² A C2-C7 SVA value of >40 mm correlates with increasing severity of disability following surgical reconstruction (Fig. 43.3).¹²

In addition to assessing radiographic alignment, it is also important to assess the location of the compressive elements and its relationship to the alignment of the spinal cord itself within the canal. In the experience of the senior author, a posterior approach can be performed regardless of radiographic alignment as long as the PSL¹³ is positive, recognizing that the ultimate goal is to

realign the spinal cord in the spinal canal. The PSL is a line drawn from the origin of the posterior laminar attachment in the middle sagittal MRI at the levels where the cord is centered in the canal (Fig. 43.4).¹³ A positive PSL indicates that there are osteoligamentous compressive structures anterior to the PSL. The PSL is independent of cervical alignment and is used to determine the

Fig. 43.4: Posterior spinal line (PSL). Point A is the cranial level where the spinal cord is centered in the canal. Point B is the caudal level where the spinal cord is centered in the canal. Point C is the laminar attachment point at the cranial level where the cord is centered in the canal. Point D is the laminar attachment point at where the caudal cord is centered in the canal. The posterior spinal line is a line connecting Points C and D. A positive PSL indicates that compressive structures are anterior and a posterior approach alone can realign the cord within the canal.

ability of the cord to center itself in the canal (Figs. 43.5A to D). A positive PSL dictates that a posterior approach would allow for posterior cord float, placing the cord parallel to the PSL and aligning it inside the spinal canal. A negative PSL indicates that there are no anterior osteoligamentous structures in front of the PSL, suggesting that an anterior approach may be necessary (Figs. 43.6A and B). Similarly, Fujiyoshi et al. described the K line as a line that connects the midpoints of the spinal canal at C2 and C7 in patients with ossification of the posterior longitudinal ligament (OPLL).¹⁴ They found that posterior shift of the spinal cord and neurologic improvement was not obtained after posterior decompression surgery in the K line negative group.¹⁴ Using the PSL to guide surgical approach emphasizes the importance of centering the spinal cord within the canal rather than correcting absolute radiographic spinal alignment. This approach is a novel one that allows for the potential of performing a posterior approach even in the setting of a slightly kyphotic spine (Figs. 43.7A and B).

Any patient undergoing a posterior procedure should also obtain a computerized tomography (CT) scan to evaluate bony anatomy. Ossification of the posterior longitudinal ligament can be detected on CT and typically pushes the surgeon toward a posteriorly based procedure secondary to the high incidence of incidental durotomy with an anterior procedure. The CT scan can also help visualize the cervical pedicles as well as the lateral masses to aid in placement of hardware posteriorly.

Figs. 43.5A to D: Representation of cases with positive PSL independent of spinal sagittal alignment. (A) Spine in lordosis with positive PSL. (B) Spine straight with positive PSL. (C) Spine in kyphosis with positive PSL. (D) Spine in S with positive PSL.

INDICATIONS

Most surgeons elect to use anterior or anterior/posteriorly procedures when the pathology is at three or less levels and the compression is secondary to focal disease at the anterior disk osteophyte complexes.¹⁵ Ideal patients for posterior only procedures include those who have diffuse narrowing behind the disks and vertebral bodies

secondary to OPLL, congenital stenosis, or more than three levels of compression. Although unusual, isolated posterior compression of the spinal cord from buckling of the ligamentum flavum or a cervical facet cyst is also a good indication for a posterior decompression. Posteriorly based techniques include laminoplasty, laminectomy alone, or laminectomy/laminoplasty and fusion. In the setting of focal anterior compression that exists simultaneously with congenital or multilevel stenosis, an anterior decompression and fusion procedure can be combined with a multilevel posterior procedure.

Laminectomy Alone

Removal of the entire lamina without reconstruction of the posterior elements is an option for treatment of CSM. Miyazaki reported the results of 155 patients who underwent laminectomy and found that 82% showed improvement based on Japanese Orthopaedic Association (JOA) scores at 1-year follow-up.¹⁶ However, longer follow-up of patients following laminectomy alone demonstrated that late neurological deterioration occurred in 23% of patients.¹⁷ A systematic literature review determined that laminectomy alone can be effective in treating CSM with limitations being increased risk of postoperative kyphosis compared to anterior techniques, laminoplasty, or laminectomy with fusion.¹⁸ Several authors have also reported kyphosis following laminectomy with Herkowitz et al.¹⁹ and Kaptain et al.²⁰ reporting a 25% and 21% incidence, respectively, at 2-year follow-up. Postlaminectomy kyphosis

Figs. 43.6A and B: Both cervical spines have kyphotic alignment based on the measurement by Toyama (green line). (A) Positive posterior spinal line (PSL) demonstrating compressive elements anterior to the PSL indicating that a posterior approach may be used. (B) Negative PSL demonstrating that there are no compressive elements anterior to the PSL indicating that a posterior approach is not recommended.

Figs. 43.7A and B: (A) Representative patient with myelopathy in the setting of a kyphotic spine (green line) and positive posterior spinal line (PSL) (red line) Preoperative sagittal and axial view. (B) Postoperative sagittal and axial view demonstrating adequate posterior cord float despite the presence of kyphosis.

Figs. 43.8A to D: (A) Magnetic resonance imaging (MRI) showing ankylosis, severe stenosis, and neutral alignment. (B) C3-C7 laminectomy without a fusion. (C) The posterior elements are removed in a monoblock manner. (D) Postoperative MRI demonstrating a widened canal and maintenance of sagittal alignment.

and instability is the most common complication following an isolated laminectomy and is one of the primary drivers for its decreased use for treatment of CSM. Interestingly, deformities of the cervical spine occurring after surgery do not always appear to cause symptoms or neurologic abnormalities.^{18,21}

Guigui et al. examined 58 patients for spinal deformity and instability after multilevel cervical laminectomy for CSM and found that at an average of 3.6-year follow-up, 31% of patients had postoperative changes in spinal alignment and 25% had destabilization at one or more levels.²¹ All of the levels destabilized on the postoperative films had instability on the preoperative dynamic radiographs.²¹ Kaptain et al. also found that kyphosis was twice as likely to occur following an isolated laminectomy if preoperative imaging studies demonstrated a straight spine.²⁰

It is our recommendation that a laminectomy procedure should be avoided when there is loss of normal cervical lordosis on the preoperative neutral lateral radiograph and if there is instability of flexion extension radiographs preoperatively. If a laminectomy requires the addition of a laminoforaminotomy with removal of >50% of the facet to decompress the cervical roots for concomitant radiculopathy, a fusion should be performed. The ideal patient for a cervical laminectomy is an elderly patient with no instability/kyphosis who has a severely degenerative spine with little risk of postoperative instability (Figs. 43.8A to D). The technique for a cervical laminectomy is covered in the laminectomy and fusion section of this chapter.

Postlaminectomy kyphosis can present as increasing neck pain, loss of horizontal gaze secondary to kyphosis, and worsening myelopathy/radiculopathy. Symptomatic

Figs. 43.9A and B: (A) 48-year-old female who underwent a laminectomy alone for myelopathy. She presented four years later with recurrent symptoms, instability, and loss of normal lordosis. (B) She subsequently underwent a four level ACDF to correct the instability and kyphosis.

postlaminectomy kyphosis should be treated with a deformity correcting fusion procedure to prevent worsening of the deformity.^{22,23} A CT and MRI should be performed to assess the amount of bone stock available for fixation as well as the degree of stenosis. The treatment of postlaminectomy kyphosis is dependent of whether the patient has a fixed or flexible deformity, and the degree of sagittal imbalance. A standing 36 inch lateral radiograph to assess spinal sagittal balance should also be obtained when planning fusion levels. Flexion/extension radiographs should also be obtained to assess the flexibility of the deformity. Flexible deformities can be treated with a revision posterior cervical fusion with lateral mass or pedicle fixation to fuse the patient in lordosis. Some authors have reported a 96% fusion rate following treatment of postlaminectomy kyphosis with wiring of the posterior facets.²² There are few clinical studies on the treatment of postlaminectomy kyphosis with modern lateral mass or pedicle fixation. This is likely secondary to the phasing out of treatment of CSM with a laminectomy alone as the awareness of postlaminectomy kyphosis or instability increases. It is our recommendation that kyphosis treated with posterior fixation alone should be carried out to the proximal thoracic spine to avoid distal junctional kyphosis.

Fixed deformities can be released with multilevel unciniate to unciniate anterior cervical discectomies and fusion (ACDF) followed by anterior structural grafting to build in cervical lordosis. This can be followed by anterior plate fixation to fuse the patient in lordosis if three or fewer levels

have been grafted or anterior and posterior fixation if more than three levels were involved. In our experience even in the setting of a fixed deformity, multilevel ACDFs can be very useful to restore lordosis and simultaneously decompress the spinal cord from disk osteophyte complexes. Occasionally, a cervicothoracic osteotomy or a posterior-anterior-posterior release can be used for severe deformities. It is our preference to restore lordosis with multiple ACDFs rather than perform posterior osteotomy, as the correction of the lordosis is more anatomical and less segmentally acute with an ACDF (Figs. 43.9A and B).

Laminoplasty

The laminoplasty procedure is a nonfusion procedure aimed at expanding the spinal canal while preserving its bony architecture. Although the Japanese popularized this technique for the treatment of OPLL,^{24,25} indications for a laminoplasty have been expanded to treating stenosis secondary to CSM or congenital stenosis. Several authors have reported a neurological recovery rate following an open-door laminoplasty to be approximately 60% with patients <60 years and with <1 year of symptoms having better results.^{26,27} Yoon et al. performed a systematic review of studies explicitly designed to evaluate the effect of preoperative factors on patient outcome after cervical laminoplasty for CSM or OPLL.²⁸ They found that hill-shaped lesions may be associated with poorer outcomes as well as patients with increased severity of disease and a longer duration of symptoms.²⁸ The senior author N.F.

Figs. 43.10A and B: Laminoplasty with (A) and without (B) the use of structural bone graft and the use of mini plates.

reported on the outcomes of 78 patients who underwent an open-door laminoplasty. Sixty-nine patients presented some improvement according to the Nurick's scale (90%), and there have been no changes in stability or postoperative alignment.¹³

Since laminoplasty is not a fusion procedure, preoperative alignment of the spine is ideally nonkyphotic so that the decompressed spinal cord can float posteriorly away from the anterior elements. Several authors have reported that a laminoplasty in a kyphotic spine leads to poorer clinical outcomes.^{29,30} Even in the setting of normal alignment, Aita et al. also found that laminoplasty can be associated with progressive kyphosis at 5-year follow-up.³¹

It is our recommendation that a laminoplasty procedure should only be performed in patients who do not have preoperative instability or at least neutral alignment of the cervical spine. This alignment should be assessed on a preoperative neutral lateral radiograph. The ideal candidate for a laminoplasty is a patient who has a neutral to lordotic spine with preserved range of motion (ROM) and multilevel stenosis.

We typically do not recommend a short segment laminoplasty (less than four levels) as retained lamina in the cranial or cephalad segments adjacent to the laminoplasty can tether the spinal cord as it drifts posteriorly. The majority of cases are a C3-C6, or C3-C7 laminoplasty. If there is compression at the inferior arch of C2 or superior arch of C7, a dome laminectomy can be performed adjacent to the laminoplasty. Although there are multiple techniques to performing a laminoplasty, it is our preference to perform an open-door laminoplasty with recon-

struction of the lamina with miniplates. Use of a structural graft is not always necessary and some surgeons use a miniplate without a structural graft to maintain the space open as the hinge side typically heals. Use of plates has been shown to maintain the opening and decrease loss of mobility and postoperative pain (Figs. 43.10A and B). This approach preserves most of the ligamentous structures that are important for maintaining stability.

Patients are positioned in the prone position with Mayfield tongs on chest rolls. Neurological monitoring using motor evoked potential and somatosensory evoked potentials is performed throughout the entire surgery. The head is positioned in a slightly flexed position to unshingle the lamina to ease drilling the laminoplasty trough. A midline incision is made; the fascia is identified. The avascular midline is exposed down to the spinous process using a cerebellar retractor to serially spread the paraspinal muscles, taking care of all ligamentous structures. Subperiosteal dissection of the lamina is performed at all levels to be released. It is critical to preserve all of the midline ligaments as well as the facet joint capsules. Exposure on the hinge side does not have to be more lateral than the lamina-facet junction. Exposure on the opening side needs to be more lateral requiring exposure of the lateral masses for miniplate fixation. On the opening side, a Cobb elevator can be used to gently expose the facet joint capsules; exposure of the lateral masses should be taken to the lateral aspect of the lateral mass taking care to preserve the joint capsules.

The decision of which side to open is arbitrary and is based on surgeon preference; it is our preference to

Figs. 43.11A and B: (A) Resection of outer cortex and thinning the inner cortex on one side with resection of the entire lamina on the contralateral side. The width of the laminoplasty is from one lamina facet junction to the other (22–24 mm) and wider than the width of a laminectomy (18 mm) for a laminectomy and fusion procedure. (B) Opening the osteotomy with a greenstick fracture of the contralateral side.

open the side that requires foraminotomies if there is concomitant radiculopathy. We measure the width of the lamina resection on preoperative imaging studies from one lamina–facet junction to the other. It should be noted that the width of a laminoplasty (22–24 mm) is greater than the width of a laminectomy (18 mm). A laminoplasty resection should be from one lamina–facet junction to the other, while a laminectomy should be limited to the width of the spinal cord to limit excessive cord float. This width is then set on calipers and a marking pen is used to draw lines on the lamina to help guide the laminoplasty trough. If a foraminotomy or a C2 dome laminectomy is needed, it is our preference to do all preliminary drilling with an AM-8 burr prior to the laminoplasty. This minimizes burr use while the spinal cord is exposed. An AM-8 3 mm acorn tip burr is then used to create the trough on the opening side at the lamina–facet junction. Since a 3 mm burr is used, the trough width is at minimum 3 mm. Once the lamina is removed, a 1 mm Kerrison is used to cut through the ligamentum flavum. A small 6-0 angled curette or micronerve hook can then be used above the spinal cord to make sure that the spinal cord is completely released from the underlying ligaments and lamina. Any epidural bleeding can be controlled with liquid gelfoam and bipolar electrocautery. The hinge side can then be created in a similar manner using an AM-8 burr. The outer cortex and inner cancellous bone should be drilled just up until the inner cortex. The inner cortex should be slowly thinned;

caution should be taken to not drill through the thin inner cortex. The trough width on the hinge side is typically 1 mm wider to allow for visualization of the inner cortex. While the surgeon is drilling the hinge side, his/her assistant is pushing the lamina from the opening side toward the closing side to test whether enough bone has been resected. Resection of the inner lamina should stop once there is enough give and the inner cortex starts to greenstick fracture. Patience should be taken during this step as the inner cortex has significant viscoelasticity and slow constant pressure on the spinous process toward the hinge side can open the canal significantly as time passes (Figs. 43.11A and B). If a complete osteotomy is unintentionally made on the hinge side, the underlying ligament is typically enough to allow the osteotomy to heal. However, if the hinge feels loose and is at risk of pushing on the spinal cord, a miniplate can be used to bridge the osteotomy as it heals (Figs. 43.12A and B). For a C3–C7 laminoplasty, access to the C2–C3 interspace is often difficult and requires undercutting the inferior aspect of the C2 lamina. Occasionally, if C2 is going to be included in the laminoplasty construct the inferior arch of C1 may need to be thinned. In this situation, the vertebral arteries should be protected by placing an instrument on the inferior arch of C1.

As the canal is expanded, dural adhesions may need to be released from the underlying dura with the use of a large ball tip probe or a Woodsen elevator. The cranial

Figs. 43.12A and B: (A) Involuntary osteotomy in the lamina of the right side of C2 repaired with a miniplate (arrow). (B) Involuntary osteotomy in the lamina of the right side of C7 with resection of the posterior arch preserving the ligaments (arrow).

and caudal end of the laminoplasty is often tethered by the adjacent soft tissues. For a C3-C7 laminoplasty, resection of the flavum between C2-C3 and C7-T1 may be needed to expand the proximal and distal ends of the laminoplasty to allow C3 and C7 to open adequately. Although some surgeons elect to use miniplates alone to hold the lamina open, it is our preference to use structural allograft with miniplates. Using polyetheretherketone (PEEK) or metallic spacers rather than structural allograft is also a possibility. Most laminoplasty systems have sizers to help determine the size of the structural allograft. The opening at the distal and proximal lamina is typically 6–8 mm secondary to soft tissue tethering, while the remaining laminar segments can be opened to 8–10 mm. It is typically useful to place grafts working from caudal to cranial or vice versa as each subsequent graft creates room for the next graft in line. It is our preference to use grafts that are already attached to the miniplates, as they are placed in the defect. Once the grafts are in place, miniplates are attached to the lamina and lateral mass with small screws (Figs. 43.13A to D). It is our preference to drill with a TPS drill with a 6 mm stop prior to placement of the screws. Screws in the lamina are typically 6 mm, while those in the lateral mass are 8–10 mm. Screws in the lateral mass can be placed perpendicular to the plate or aimed slightly cranially in the style of a lateral mass screw to avoid violating the facet. Postoperatively, patients can be placed in a soft cervical collar for 2–6 weeks. Extended collar wear is not needed because the laminoplasty is not a fusion procedure.

A laminoplasty can be combined with an ACDF when there is congenital stenosis or multilevel compression in the presence of a hill-shaped lesion or a large anterior disk at one or two levels. In this situation, some surgeons begin with a multilevel laminoplasty to create room for the spinal cord. This is followed by a one or two level ACDF to safely remove the compressive anterior lesion. This approach is also useful if there is segmental kyphosis as the ACDF can be used to create lordosis. Combining a short segment ACDF with a laminoplasty avoids the need to fuse every stenotic level (Figs. 43.14A to F). It should be noted that the senior author has anecdotally noticed the resolution of anterior soft disk herniations following a posterior only decompression at 6 months postoperatively. This is most likely secondary to the pulsating effect of the CSF on the disk after the canal is decompressed and is an option when there is anterior compression from a disk herniation in the setting of multilevel cervical stenosis (Figs. 43.15A to C).

Axial neck symptoms following laminoplasty has been reported by several authors.^{32,33} Hosono et al. reported on the results of 72 patients treated for CSM with laminoplasty at an average follow-up of 40 months.³² Of all patients, 60% had postoperative axial symptoms, and in 25% of patients, the chief complaints after surgery were related to axial symptoms for >3 months.³² Some authors have proposed that preservation of the C7 spinous process³⁴ or the semi-spinalis cervicis insertion onto C2³⁵ can reduce postoperative neck pain. We believe that respecting as many ligaments as possible is critical to reducing neck pain.

Figs. 43.13A to D: A 57-year-old male with weakness in arms/legs, balance problems and difficulty with fine motor skills. (A) Neutral X-ray with adequate lordosis. (B) Magnetic resonance imaging (MRI) showing multilevel stenosis. The patient underwent a C3-C7 laminoplasty. 1 year postoperative with maintenance of range of motion from flexion (C) to extension (D).

Some surgeons prefer to perform a laminoplasty to decompress the canal and perform a simultaneous fusion. This can be performed with custom lateral mass screws that thread through the laminoplasty plates. The screws can then be connected using a rod. Theoretical advantages of this technique include the ability to preserve midline anatomy as well as potentially limit posterior cord drift when compared to a complete laminectomy.

Laminectomy and Fusion

Kyphosis and instability following an isolated cervical laminectomy has led to many authors recommending a fusion if a laminectomy is performed.²¹ Early reports on the clinical outcomes of fusions performed with either

uninstrumented or instrumented (sublaminar wiring) techniques demonstrated good clinical outcomes.^{36,37} Kumar et al. reported on the outcomes of 25 patients treated for CSM by laminectomy, and lateral mass screw and plating with at least 2-year follow-up and reported no development of kyphosis or instability with 76% having improved myelopathy scores.³⁸ Houten et al. also found that at 30-month follow-up, no changes in cervical alignment occurred between the preoperative and 5.8-month follow-up X-rays.³⁹ The JOA score improved in 97% of patients from a mean of 12.9 preoperatively to 15.6 postoperatively.³⁹ Other authors have reported up to a 97% fusion rate with laminectomy and fusion with lateral mass screw and plate fixation at a mean of 15-month follow-up.⁴⁰ Contemporary techniques for cervical fusions include the

Figs. 43.14A to F: A 76-year-old male with minimal neck pain and a two years history of problems with fine motor skills, diffuse trunk numbness and bilateral upper extremity weakness. Magnetic resonance imaging (MRI) (A and B) and computed tomography (CT) (C) demonstrate a large calcified disk fragment with severe cord compression at C3/4 with simultaneous diffuse stenosis. (D) The patient underwent a Stage I: C3–C7 laminoplasty followed by a Stage II: C3–C5 ACDF, C4 hemicorp. (E and F) Postoperative computed tomography demonstrating resolution of C3/C4 compression and a wider central canal from C3–C7.

(C) 6 months s/p C3-C6 laminoplasty with a postoperative MRI demonstrating resolution of the disk fragment.

use of lateral mass screw and rod fixation. The use of lateral mass screws has been associated with a considerably low rate of complications even in the setting of bicortical screw purchase.⁴¹ Complications include nerve root injury (0.6%), facet violations (0.2%), broken screws (0.3%), screw loosening (1.1%), infection (1.3%), and pseudarthrosis (1.4%).⁴¹ It is our preference to instrument the subaxial spine with lateral mass screws and rods and this is the technique that will be reviewed in this section. It should be noted that at the time of this publication the use of lateral mass and pedicle screws in the cervical spine is not approved by the US Food and Drug Administration.

Indications for a laminectomy and fusion include those patients who cannot undergo a laminoplasty because of kyphosis, instability, or resection of >50% of the facets during foraminotomies. Patients who undergo a laminectomy and fusion still need to have lordosis at the completion of the fusion. This means that patients who are able to achieve lordosis on extension but have neutral alignment on a lateral view are good candidates for a fusion as the fusion can hold the patient in lordosis. In patients with neutral alignment or slight kyphosis, the neck can

be positioned and fused in lordosis once the laminectomy is completed prior to locking the rod to the screws (Figs. 43.16A to E). However, in the setting of significant kyphosis or instability, an anterior posterior procedure may need to be performed. Multilevel ACDFs either instrumented or uninstrumented can be used to create anterior column support and lordosis. Once lordosis is achieved, a posterior laminectomy and fusion can then be performed (Figs. 43.17A to C).

The levels chosen for the laminectomy typically include all of the stenotic levels seen on imaging studies. In order to prevent distal junctional kyphosis, the distal extent of the fusion is carried out one additional level past the last laminectomy level. For example, a C3-C6 laminectomy should be combined with a C3-C7 fusion. Some authors advocate not stopping the fusion at C7, as it leaves the cervicothoracic junction open. It is our experience that in the setting of instability at C7/T1, the fusion should be carried to T1. It is currently our preference to carry the distal extent of the fusion to T1 in most cases.

The surgical technique begins in a similar patient position as the laminoplasty. Exposure needs to include the

Figs. 43.16A to E: (A to D) A 47-year-old Asian female with left sided weakness and myelopathy. Magnetic resonance imaging (MRI) and computed tomography (CT) demonstrating stenosis and ossification of the posterior longitudinal ligament (OPLL). Neutral radiograph demonstrates neutral alignment and loss of normal lordosis. Extension X-ray demonstrates ability to achieve lordosis. (E) C3 to C6 laminectomy and C3 to C7 fusion with maintenance of lordosis with the fusion.

Figs. 43.17 A to C: (A) A 66-year-old female with myelopathy. Neutral X-ray with loss of lordosis. (B) Magnetic resonance imaging (MRI) with central stenosis and a negative posterior spinal line in green. (C) Stage 1: Anterior cervical discectomy and allograft placement at C4/C5 and C5/C6. Stage 2: Posterior cervical laminectomy and fusion from C3 to C7 with lateral mass and pedicle screw instrumentation.

lateral aspect of each lateral mass and facet joints to be fused. We prefer to drill and prepare the holes for each lateral mass prior to the laminectomy to avoid passing instruments over an exposed spinal cord. A 2-mm round burr is then used to decorticate each facet joint. The center of each lateral mass is identified, and a 2-mm round burr is used to make a pilot hole. A drill with a 14 mm stop is

then used at the starting point and drilled in an upward and outward technique according to the Roy Camille technique. Typically, the appropriate angulation involves the drill touching the spinous process of the inferior vertebrae being instrumented. Some surgeons prefer to place lateral mass screws in a bicortical manner. In this situation, a depth stop is not used as the surgeon has a tactile

sensation when crossing the second cortex of the lateral mass. It should be noted that the exiting nerve is at risk when placing a bicortical screw (i.e. C5 nerve with a C5 lateral mass screw). A ball tip feeler can be used to confirm that each drilled hole has four walls prior to screw placement. Liquid gelfoam or Floseal can also be pressurized into the tapped hole to ensure that it has a floor. Extravasation around the lateral mass or into the facet joint indicates that there may be a bony defect present. It is our preference to tap each hole prior to screw placement to avoid cracking the lateral mass during screw insertion. Pedicle screws are typically placed at the distal extent of the fusion (C7 or T1 pedicle screw). This chapter is covered elsewhere in this book.

Once the screw holes are prepared, the laminectomy is performed. The width of the laminectomy is based on the width of the spinal cord measured from axial MRI and CT images and is typically 18 mm. The width of the laminectomy can be set with calipers and marked using a surgical marker on the lamina as a guide. The laminectomy is then performed using an AM-8 acorn tip burr. The outer lamina, cancellous bone, and inner lamina can be drilled up until the ligamentum flavum. A 1-mm Kerrison can then be used to scissor up the troughs to separate the flavum from the dura. At this point, the lamina should be removed as one unit in an en bloc manner. This is performed by taking towel clamps and attaching them to each spinous process. The lamina is removed from caudal to cranial using a large angled ball tip probe to separate dural adhesions from the lamina. It is typically difficult to separate the laminar block at C2-C3 (for a C3-C7 laminectomy) from C2. Gently placing pressure inferiorly on the block of lamina can typically unshingle and separate the C3-C7 lamina from C2. Hemostasis can be achieved with liquid gelfoam.

Once the laminectomy is performed, the lateral mass screws typically (3.5 mm by 14 mm) are placed in the prepared holes. At this point, the surgeon should unscrub and position the neck in lordosis using the Mayfield tongs and table clamps. The degree of lordosis can be assessed using fluoroscopy. Contoured lordotic rods are then final tightened to the tulip heads. Local autograft bone from the posterior elements is ground and mixed with allograft and placed over the decorticated lateral masses and facet joints. Patients are instructed to wear a rigid, semirigid collar or soft collar for at least 6 weeks postoperatively.

OUTCOMES

There are few clinical studies comparing the treatment of anteriorly versus posteriorly based procedures for CSM.

Fang et al. reported on the clinical and radiologic outcomes between expansion open-door laminoplasty with foraminotomy and ACDF in the treatment of coexisting multilevel CSM and unilateral radiculopathy.⁴² A total of 110 patients were followed for >3 years, and in the laminoplasty group, there was shorter operative time, less blood loss, and fewer complications than the ACDF group. Both groups had similar neurological recover based on JOA scores.⁴² There are few clinical studies comparing posteriorly based procedures. Yukawa et al. reported on the results of one prospective randomized study comparing laminoplasty to skip laminectomy.⁴³ Patients in both groups had 80% of the preoperative ROM in both groups, and there were no differences in JOA scores or axial neck pain.⁴³ In a small matched cohort study, Heller et al. compared 13 patients who had laminoplasty to 13 patients with laminectomy and fusion for multilevel CSM with approximately 2-year follow-up. The laminoplasty group had greater subjective improvement in strength, dexterity, sensation, pain, and gait.⁴⁴ Interestingly, the presence of axial neck pain was the same in both groups.⁴⁴ Yoon et al. performed a systematic review comparing outcomes of laminoplasty versus a laminectomy and fusion.⁴⁵ For patients with CSM, there is evidence that suggests that laminoplasty and laminectomy and fusion procedures are similarly effective with similar safety profiles. Higher-quality research is necessary to more clearly delineate when one procedure is preferred compared with the other.⁴⁵

COMPLICATIONS

Other than hardware complications, postoperative C5 nerve root palsy is one of the most common neurological complications. A C5 palsy presents as deltoid or biceps weakness and typically presents in the first postoperative week though it has been reported to vary between immediately to up to 2 months after surgery.⁴⁶ C5 palsy has been reported with both anterior and posterior procedures and is postulated to be secondary to traction on the C5 nerve from spinal cord float. Dai et al. reported a rate of 12.9% following a laminectomy with the most frequent pattern being C5 or C6; the mean time for recovery was 5.4 months.⁴⁷ Bydon et al. examined the incidence and prognostic factors of C5 palsy in 1001 anterior and posterior cases and reported an 8.6% incidence in posterior procedures.⁴⁸ After approximately 2 years, C5 palsies improved in 89% of patients. Older age was the strongest predictor of C5 palsy.⁴⁸ In a large scale systematic review, Gu et al.

found that risk factors for a C5 palsy include patients with excessive spinal cord drift, pre-existing foraminal stenosis, OPLL, laminectomy (rather than laminoplasty), and male gender.⁴⁶ Katsumi et al. studied the characteristics of the foramen in patients with and without a C5 palsy in 141 patients who underwent a laminoplasty.⁴⁹ They reported that the average diameter of the C4/C5 foramen was 1.99 mm in the palsy group and 2.76 mm in the nonpalsy group, suggesting that the etiology of C5 palsy is impairment of the C5 nerve root induced by pre-existing C4/C5 foraminal stenosis.⁴⁹ The same group evaluated the effectiveness of a prophylactic C4/C5 foraminotomy with open-door laminoplasty in 141 patients with CSM and found that the incidence of C5 palsy was 1.4% in the foraminotomy group versus 6.4% in the nonforaminotomy group.⁵⁰ They concluded that a prophylactic foraminotomy was an effective preventive measure against postoperative C5 palsy after laminoplasty.⁵⁰ Since the majority of C5 palsies resolve, treatment involves patient education as well as passive ROM of the shoulder to prevent a frozen shoulder. There is no data regarding use of epidural or systemic steroids to prevent or shorten the course of C5 palsy. In the setting of a very dense C5 palsy, some surgeons perform a C4/C5 foraminotomy postoperatively to try to give the nerve as much room as possible to recover.

It is critical to limit the width of the laminectomy in a laminectomy fusion procedure to the width of the spinal cord (18 mm). A wider laminectomy and greater posterior cord drift has been associated with an increased risk of postoperative C5 palsy in multiple clinical studies.^{51,52} The laminectomy width is typically greater in laminoplasty procedures, as the laminoplasty trough is made from one lamina-facet junction to another. We currently perform a C4/C5 foraminotomy either through an ACDF or a posteriorly when a laminectomy/fusion or laminoplasty is performed in the setting of a pre-existing stenotic C4/C5 foramen.

KEY POINTS

- A posterior procedure for CSM is ideally performed in the presence of a lordotic spine so the spinal cord can float away from the posterior elements once released. However, if the PSL indicates that there are compressive elements anterior to it, then a posterior approach may be considered despite the presence of kyphosis with the understanding that the cord will be realigned in the canal.

- A laminectomy alone without a fusion is generally not recommended secondary to the risk of postlaminectomy kyphosis. Ideal patients for a laminectomy alone have a very spondylotic or ankylosed spine to minimize the risk of kyphosis and instability.
- Patients who are candidates for a laminoplasty have a neutral to lordotic spine, minimal spondylosis, and a congenitally small canal. The laminoplasty trough (22–24 mm) should be wider than a laminectomy trough (18 mm) and is measured from one lamina-facet junction to the other. Reconstruction with spacers and miniplates is preferred following a laminoplasty for stability.
- Patients who do not have lordosis but can achieve lordosis on an extension radiograph are candidates for a laminectomy and fusion. Significant kyphosis can be corrected with multilevel ACDFs followed by a posterior laminectomy and fusion. The distal fusion level should be one level below the last laminectomy level to prevent distal junctional kyphosis.
- A postoperative C5 palsy is the most common complication and can be minimized by performing a C4/C5 foraminotomy during the posterior procedure if there is pre-existing foraminal stenosis. In the setting of a laminectomy and fusion, a postoperative C5 palsy can be minimized by limiting the laminectomy width.

INTRODUCTION

Ossification of the posterior longitudinal ligament (OPLL) involves pathologic calcification of the posterior longitudinal ligament anywhere along the length of the spinal column with the cervical region being the most commonly affected. Because it is a space occupying lesion within the spinal canal, the spinal cord may be compressed leading to various neurologic deficits with cervical myelopathy being the most common. Patients with overt neurologic manifestations of OPLL are usually treated with decompression of the spinal cord from either an anterior or posterior approach, with some patients needing a combined procedure. Although the exact pathogenesis and natural history are not fully elucidated, there have been great strides in these areas over the recent years.

Tsuyama, has reported on the incidence of OPLL: 2.4% in Asian populations and 0.16% in non-Asian populations. The highest rates of OPLL are found in Japan and it is more than twice as common in men than women, with symptomatic OPLL usually presenting in the 5th to 6th decade of life. Ossification of the posterior longitudinal ligament was previously considered to be specific to Asian people but now some studies believe OPLL is a subtype of diffuse idiopathic skeletal hyperostosis,²⁻¹⁰ which is well known

in the United States and Europe. There have also been reports of OPLL in conjunction with ankylosing spondylitis and other spondyloarthropathies.^{11,12} Other patient populations have also shown the development of OPLL. Maiuri et al.¹³ reported on eight Italian patients with OPLL and Matsunaga et al.¹⁴ reported a 20% incidence in patients with schizophrenia.

In terms of the pathology of OPLL, it is believed to form through endochondral ossification. The histopathology was described by McAfee et al.⁹ in which OPLL is composed mostly of lamellar bone with mature Haversian canals. The study of the ligamentum flavum in patients with OPLL revealed atrophic elastic bundles with a two-layer structure, disappearance of microfibrils, irregular alignment of collagen fibrils, and many extracellular plasma membrane-invested particles that resemble matrix vesicles.¹⁵

PATHOGENESIS

Numerous studies have examined the poorly understood pathogenesis of OPLL. Results point to a combination of genetic and environmental factors that contribute to the formation of OPLL. Ishida and Kawai¹⁶ studied cell lines from nonossified sites in patients with OPLL and

Table 44.1: Summary of notable genes, transcription factors, and cytokines implicated in ossification of the posterior longitudinal ligament pathogenesis.

Gene	Protein	Chromosome	Physiological function
<i>NPPS</i>	Nucleotide pyrophosphatase	6	Regulates soft-tissue calcification and bone mineralization via the production of PPi, a known inhibitor of calcification
<i>COL11A2</i>	$\alpha 2$ chain, Type XI collagen	6	Associates w/Type II collagen and is responsible for forming the size, diameter and growth rate of fibril networks, forms extracellular matrix scaffolds and may contribute to the formation of ectopic bone by enhancing endochondral ossification
<i>COL6A1</i>	$\alpha 1$ chain, Type VI collagen	21	Forms extracellular matrix scaffolds and may contribute to the formation of ectopic bone by enhancing endochondral ossification
<i>BMP-2</i>	BMP-2	20	Stimulates proteoglycan formation and alkaline phosphatase activity in chondroblasts and osteoblasts and defects cellular differentiation
<i>TGFβ</i>	TGF β 1	19	Mediates bone development and metabolism

found that they have high alkaline phosphatase activity, response to calcitonin, and calcitriol. An immunohistochemical study of extracellular matrix in the twy mouse (tiptoe walking Yoshimura—an animal model for OPLL) shows that degeneration and subsequent herniation of the intervertebral disc is a significant factor in initiating OPLL formation. At 14 weeks, the discs that herniated into the thickened posterior longitudinal ligament caused cartilaginous tissue to form within the ligament, as if to repair the disc degeneration.¹⁷

Hypertrophy of the posterior longitudinal ligament is also thought to be an early stage of OPLL. One study showed that the hypertrophied ligament exhibited very similar characteristics of OPLL in terms of hyaline degeneration, proliferation of chondrocytes and fibroblast-like spindle cells, infiltration of vessels and small ossification, and staining by BMP, TGF- β , and proliferating cell nuclear antigen.¹⁸

Numerous genetic factors have been implicated in the formation of OPLL (Table 44.1).¹⁹ The proteins made from these genes have been shown to be crucial in the regulation of chondrogenesis, osteogenesis, or bone mineralization. Okawa et al.^{20,21} performed a genetic analysis of two mice and found a single-base mutation in the *NPPS* gene that results in loss of more than one-third of the native *NPPS* enzyme. Nucleotide pyrophosphatase (*NPPS*) is a type II transmembrane metalloenzyme that regulates soft-tissue calcification and bone mineralization via the production of PPi,²² a known inhibitor of calcification.²³ There are at least three isoforms of *NPPS* in humans with the *NPP1* subtype being implicated in OPLL pathogenesis.²⁴

This subtype generates PPi in osteoblasts and chondrocytes and regulates bone mineralization by decreasing hydroxyapatite crystal deposition.²³ Although not fully understood, when extracellular PPi levels are low, pathologic calcification of ligaments and joints occur. In a later study by Tahara et al.,²⁵ the authors showed that *NPPS* and leptin receptor genes do not promote an increased susceptibility to OPLL, but are associated with the extent of heterotopic ossification. Horikoshi et al.²⁶ also could not demonstrate the association between the *NPPS* gene and OPLL.

Many collagen genes have also been studied, including human collagen $\alpha 2$ gene (*COL11A2*). Koga et al.²⁷ showed that this gene, located on chromosome 6p close to the human leukocyte antigen region, is strongly associated with OPLL. Retaining exon 7 together with removal of exon 6 in the *COL11A2* gene could play a protective role in the ectopic ossification process.²⁸ Maeda et al.²⁹ reported a sex specific association of the *COL11A2* haplotype with OPLL in male patients. However, a recent study by Horikoshi et al.²⁶ could not reproduce the association between this gene and OPLL.

A single nucleotide polymorphism in the collagen 6A1 gene (*COL6A1*) has been shown to be associated with OPLL.^{30,31} Kong et al.³² studied the Han Chinese population and found a significant association of *COL6A1* with OPLL. They demonstrated that three single-nucleotide polymorphisms are significantly associated with the formation of OPLL and ossification of the ligamentum flavum.

Bone morphogenetic protein, BMP-2, a substance with the ability to induce ectopic bone, is believed to play an important role in the pathogenesis of OPLL. Bone

morphogenetic protein receptors are increased in ossified ligament tissue in patients with OPLL.³³ Bone morphogenetic protein-2 stimulates differentiation of ligament cells in patients with OPLL, and both induces ossification by increasing alkaline phosphatase activity and stimulating DNA and procollagen type I carboxyl-terminal peptide synthesis.³⁴ The TC and CC genotypes in the BMP-2 gene of male Han Chinese patients have a genetic susceptibility to OPLL in the cervical spine.³⁵

Transforming growth factor- β has also been studied in the literature. The T869°C polymorphism of the TGF- β 1 gene is a genetic determinant of a predisposition to OPLL.³⁶ Kawaguchi et al.³⁷ later demonstrated that the TGF- β 1 polymorphism is not associated with OPLL development, but rather a factor related to the extent of ossification. Patients with the T869°C allele polymorphism frequently have OPLL in the cervical, thoracic, and/or lumbar spine.

In addition to the above genetic products influencing OPLL, numerous other studies have shown various biomarkers that were upregulated in the sera of OPLL patients.^{33,38-43} There is also evidence that noninsulin-dependent diabetes mellitus may be a risk factor of OPLL.⁴⁴

Environmental factors have also been implicated in the formation of OPLL. Mechanical stress in ligaments of the spine has been investigated as a cause of OPLL development and progression.⁴⁵ Prostacyclin synthase levels in ligament cells from OPLL patients have been shown to be elevated after applying mechanical stress and induced osteogenic differentiation via the PGI₂/cyclic adenosine monophosphate pathway.⁴⁶ Mechanical stress also induces mRNA expression of alkaline phosphatase, osteopontin, BMP-2, BMP-4, BMP receptors,⁴⁷ and mRNA expression of Cbfa1, type I collagen, osteocalcin, integrin β 1,⁴⁸ and endothelin-1.⁴⁹ The P2Y1 purinoceptor subtypes, intensively expressed in OPLL cells, responded to mechanical stress induced extracellular adenosine triphosphate, which stimulated OPLL progression.⁵⁰

Other environmental associations with OPLL include frequent consumption of pickles, nondaily consumers of rice,⁵¹ family history of myocardial infarction, high body mass index at age 40, long working hours, and working night shifts.⁵² In contrast, frequent consumption of chicken and soy products⁵³ and proper sleeping habits (6–8 hours/night) in the prime of life may decrease the risk of OPLL.

■ NATURAL HISTORY

The natural history of OPLL was investigated by Matsunaga et al.⁵⁴ in which 450 patients with OPLL were followed for at

least 10 years with a mean follow-up of 17.6 years. Only 17% of patients without myelopathy at the first visit developed myelopathy during the follow-up period. The myelopathy-free rate in these patients was 71% after 30 years according to Kaplan–Meier analysis. The researchers suggested that prophylactic surgery in patients without symptoms of myelopathy is unnecessary. This same group of authors⁵⁴ studied predictors for development of myelopathy in 156 patients with OPLL from 16 spine institutes with an average follow-up period of 10.3 years. They found that both static and dynamic factors were related to the development of myelopathy.³⁹ Patients with >60% spinal canal stenosis on plain radiography developed myelopathy. They concluded that 60% spinal canal stenosis by OPLL and lateral deviated-type OPLL on computerized tomography (CT) scan (Figs. 44.1A to C) were radiographic risk factors for development of myelopathy. Range of motion was also significantly greater in patients with myelopathy.

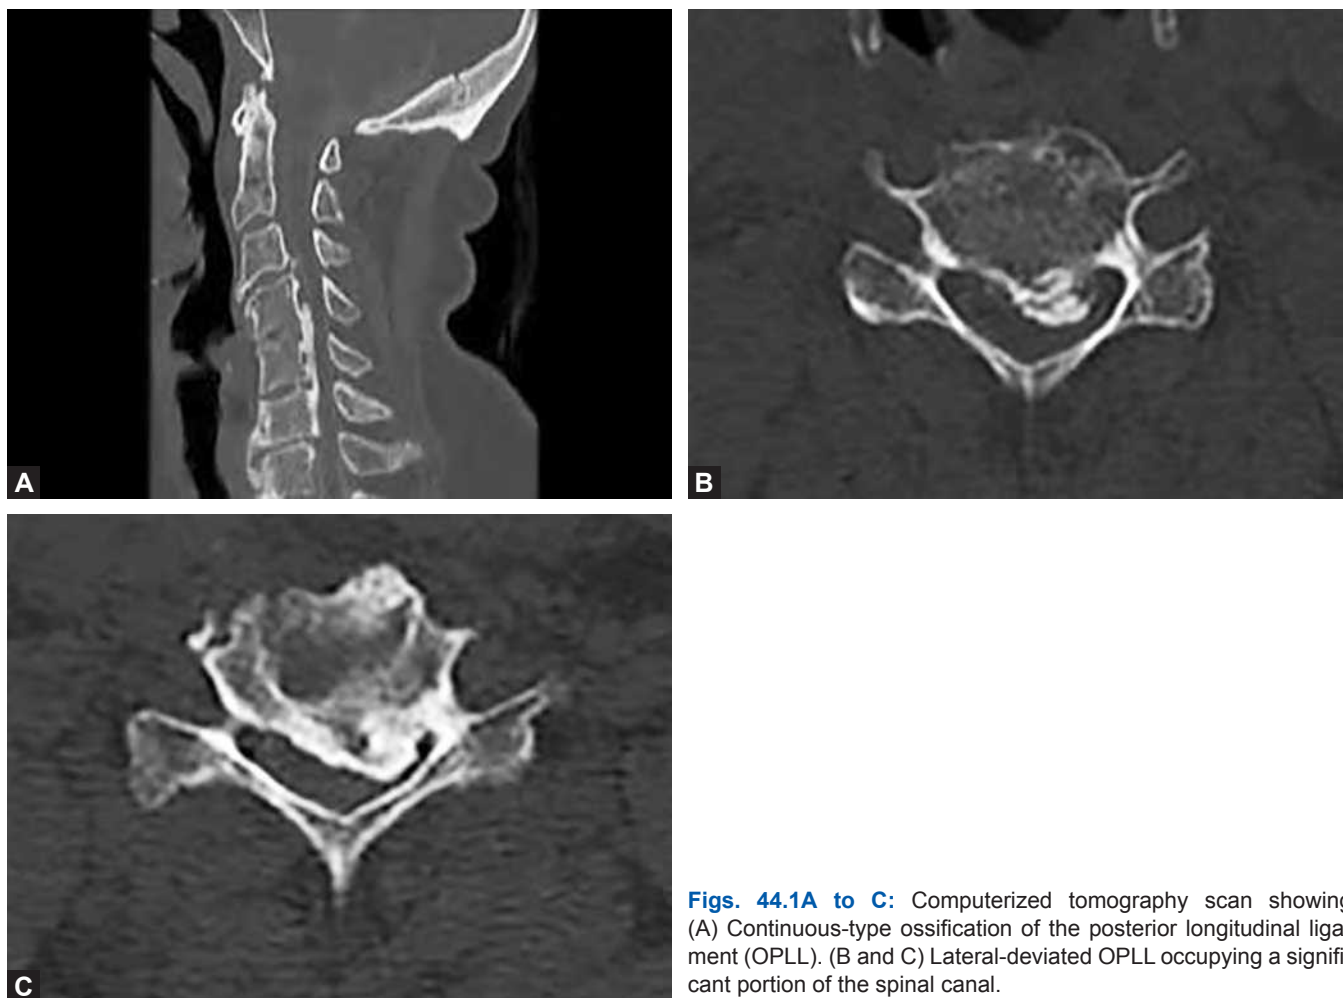

Both Chiba et al.⁵⁵ and Hori et al.^{56,57} looked at progression of OPLL. Both found that progression was more common in younger patients with continuous- and mixed-type OPLL.

■ CLASSIFICATION

The Investigation Committee on OPLL of the Japanese Ministry of Public Health and Welfare described the OPLL classification that is most widely used in the literature.⁵⁸ Based on lateral plain radiography, cervical OPLL can be classified into four types (Figs. 44.2A to D)⁵⁹: continuous, segmental, mixed, or circumscribed type. Continuous type is classified as a long lesion extending over several vertebral bodies. Segmental type is classified as one or several separate lesions behind the vertebral bodies. Mixed type is classified as a combination of continuous and segmental types. Circumscribed type is classified as the lesion mainly located posterior to a disc space.

■ CLINICAL PRESENTATION

Early in the course of the disease, most OPLL patients are asymptomatic, have mild pain and discomfort, or complain of mild numbness in their hands. As the OPLL lesion progresses, symptoms increase in severity due to compression of the spinal cord and/or nerve roots. Various presentations of OPLL occur from hand dysesthesia and tingling to hand clumsiness and gait disturbance with frank myelopathy. About 80–85% of OPLL patients experience a

slow progression, but even relatively mild injuries may suddenly aggravate symptoms or even cause quadriplegia.

Radiological Evaluation

Plain radiography is the most basic method for detecting OPLL, but it is very limited in its ability to pick up all cases or the extent of ossification. Chang et al.⁶⁰ reported that lateral radiography has poor inter- and intraobserver reliability for OPLL classification, especially for continuous-type OPLL.

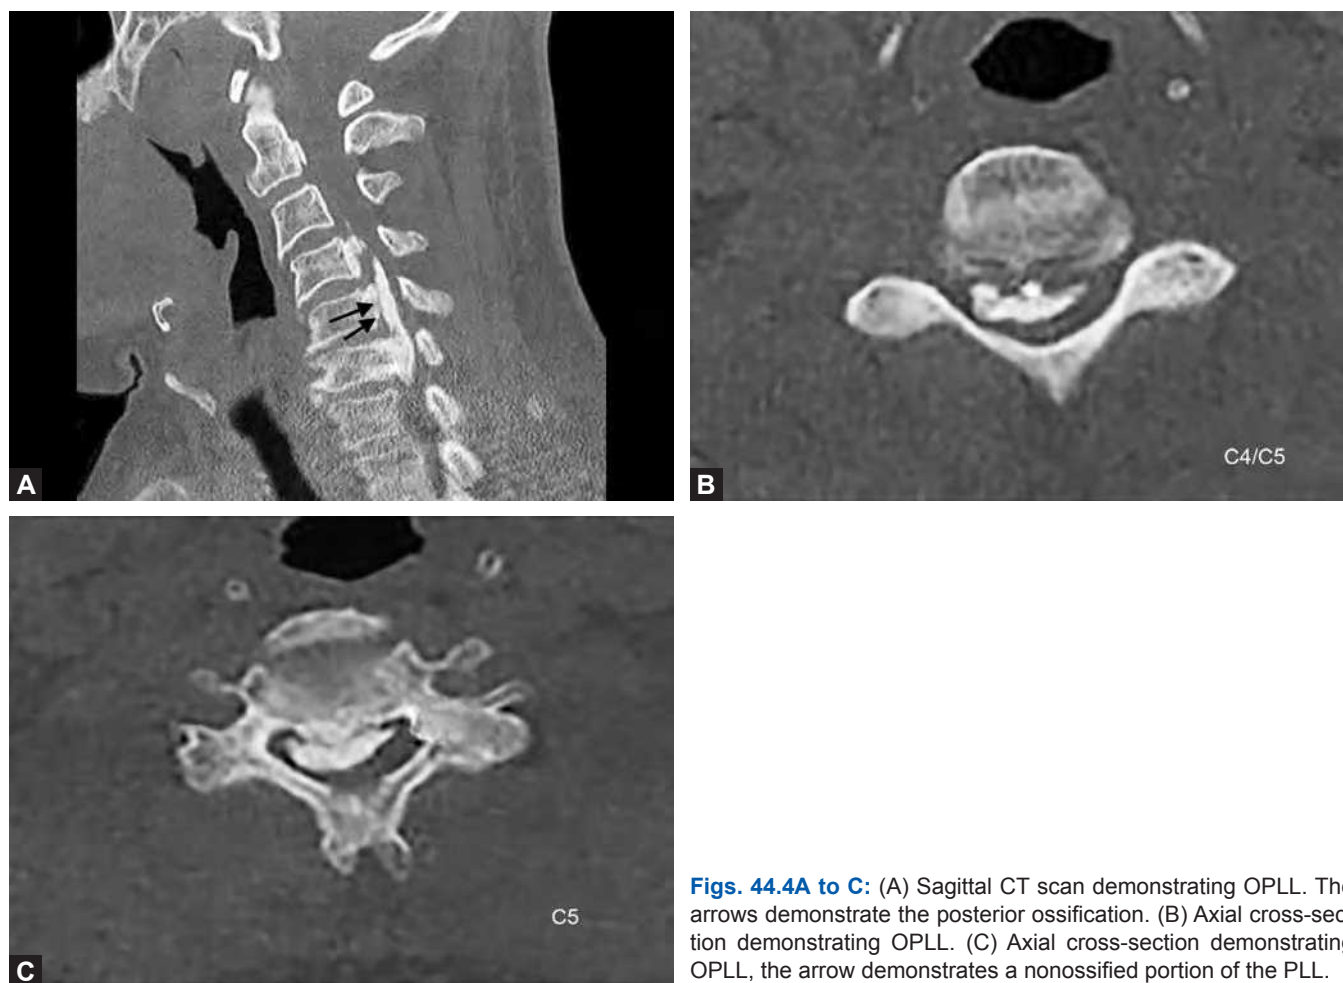

Computed tomography with or without myelography is the most useful study to show the extent and location of OPLL. It accurately depicts the severity of canal stenosis and the exact dimensions of the disease (Figs. 44.3A and B). Axial CT scan characteristically shows a sharp radiolucent line between the posterior vertebral body and the ossified ligament as well as a hill or mushroom shape of ossification.⁶¹

Dural ossification poses a particular problem in OPLL because anterior decompression may have a significant incidence of new neurological deficits and iatrogenic cerebrospinal fluid (CSF) leak. Computerized tomography scan is useful in detecting dural ossification, preoperatively. A retrospective review performed by Mizuno et al.⁶² evaluated the relationship between dural ossification and preoperative imaging. Bone window CT scans were found to be the best method for detecting dural ossification

and magnetic resonance imaging (MRI) was found to be ineffective. Nonsegmental type was found to be the most likely to have dural ossification. Two types of dural ossification patterns, double- and single-layer sign, were described by Hida et al.⁶³ based on the bone window CT images. Single layer sign was defined as a large focal mass of uniformly hyperdense OPLL. Double-layer sign was defined as anterior and posterior rims of hyperdense ossification separated by a central hypodense mass (Figs. 44.4A to C). This hypodense mass is the hypertrophied but nonossified posterior longitudinal ligament. Dural defects, during surgical decompression, were detected in 10 of 12 patients with double-layer sign and only 1 of 9 patients with single-layer sign. This finding was confirmed by Epstein;⁶⁴ a single layer sign indicated a clean dural plane with a low incidence of dural defect. Min et al.⁶⁵ studied cervical OPLL in 197 patients who underwent anterior decompression and fusion. This study also served to confirm the importance of the double-layer sign indicating dural ossification with 20 of 38 patients having dural defects and only 3 of 22 patients having defects with single-layer sign.

Min et al.⁶⁶ also found that dural ossification is even more common in thoracic OPLL with a rate of 80%. They also showed that dural ossification was detected in both nonsegmental and segmental types in the thoracic spine. Magnetic resonance imaging is sensitive for detecting soft tissue abnormalities, but is not adequate for diagnosing small ossified lesions in the spinal canal.⁶⁷ Ossification of the posterior longitudinal ligament is hypointense on both T1- and T2-weighted MRI. Characteristic findings on MRI are shown in Figures 44.5A and B. Koyanagi et al.⁶⁸ found that disc protrusion was found at the maximal compression level in 60% of patients with cervical OPLL and is more common in segmental OPLL, with an incidence of 81%. It was concluded that MRI is useful for determining the level of spinal cord compression and for helping determine the best method of surgical treatment.

Signal hyperintensity of the spinal cord on T2-weighted images were correlated with more severe neurological deficit in patients with OPLL.⁶⁸ In another study, Yagi et al.⁶⁹ found a positive correlation between postoperative expansion of the high signal intensity area of the cord and poor neurological outcome of patients with cervical OPLL. Spinal instability was found to be a risk factor for this expansion. Magnetic resonance imaging is also useful for determining the cross-sectional shape of the spinal cord at the level of maximum compression. Three shapes were

Figs. 44.4A to C: (A) Sagittal CT scan demonstrating OPLL. The arrows demonstrate the posterior ossification. (B) Axial cross-section demonstrating OPLL. (C) Axial cross-section demonstrating OPLL, the arrow demonstrates a nonossified portion of the PLL.

Figs. 44.5A and B: T2 magnetic resonance imaging showing low signal intensity of the ossification of the posterior longitudinal ligament (OPLL) lesion and significant compression of the spinal cord with increased signal intensity at the point of maximal compression. (A and B) Severe spinal cord compression and OPLL.

classified by Maysuyama et al.⁷⁰ as boomerang, teardrop, or triangular. The recovery rate after laminoplasty was the worst for patients with a triangular shape and the best for the teardrop shape. The boomerang shape was intermediate. The triangular shape had the least expansion postoperatively that correlated with a poor outcome.

Ossification of the posterior longitudinal ligament has also been described to occur at multiple locations. Park et al.⁷¹ found thoracic tandem ossification in 23 out of 68 patients with cervical OPLL. The authors recommended imaging the thoracic spine in any patient undergoing cervical OPLL surgery.

CONSERVATIVE MANAGEMENT

Although surgical treatment is the mainstay of treatment for moderate-to-severe OPLL with myelopathy, observation is an option in asymptomatic or mildly symptomatic

Table 44.2: Advantages and disadvantages of surgical procedures for cervical OPLL.

<i>Surgical procedure</i>	<i>Advantages</i>	<i>Disadvantages</i>
Laminectomy	Simple, less operative time and blood loss, low immediate complication	Risk of OPLL progression; risk of kyphotic deformity, spinal instability, and neurological deterioration due to scar tissue formation; ineffectiveness in cases w/severe kyphotic deformity and large OPLL
Laminectomy w/fusion	Relatively simple, low complication rate, decreased risk of kyphotic deformity and spinal instability	Risk of OPLL progression, ineffectiveness in cases w/severe kyphotic deformity and large OPLL
Laminoplasty	Relatively simple, low complication rate compared w/ant approach, decreased risk of kyphotic deformity, spinal instability and neurological deterioration due to scar tissue formation compared w/laminectomy alone	Risk of OPLL progression, limited effectiveness in cases w/severe kyphotic deformity and large OPLL
Ant approach	Direct ant decompression of OPLL	High complication rate (particularly neurological deterioration, graft complication, and CSF leakage), limitation in cases w/long segment OPLL or OPLL involving C-2
Combined Ant and Post approach	Direct and decompression of OPLL	More operation time and blood loss

(OPLL: Ossification of the posterior longitudinal ligament, Ant: Anterior, Post: Posterior).

patients. Pham et al.⁷² evaluated the conservative management of OPLL. They discovered that patients who present without myelopathy have a high chance of remaining progression free; however, those who already have signs of myelopathy at presentation may benefit from surgery due to a high rate of progression over continued follow-up. Effective medical treatment is still lacking for OPLL and further research is needed to elucidate targets of medical therapy. Currently, there are only symptomatic treatments such as pain medications, anti-inflammatory drugs, antidepressants, and anticonvulsants as well as rest, physical therapy, and soft collar.

SURGICAL TREATMENT OF CERVICAL OPLL

The cervical spine is the most common location for OPLL; thus, there is an abundance of literature with various surgical techniques for treating the condition. Described techniques include the posterior approach (laminectomy, laminectomy with instrumented fusion, laminoplasty), the anterior approach [anterior cervical discectomy and fusion (ACDF), anterior cervical corpectomy with fusion, open-window corpectomy, oblique corpectomy, skip corpectomy, and anterior decompression via a transvertebral approach], and the combined anterior and posterior

approach. Table 44.2 summarizes the advantages and disadvantages of each approach.⁵⁹

Posterior Approaches

Laminectomy alone is the simplest approach to decompress the spinal cord. However, if fusion is not performed, progression of kyphotic deformity has been reported. The progression did not affect neurologic outcomes as shown in several studies.^{73,74} Kato et al.⁷⁴ also found that OPLL progressed in 70% of patients that underwent laminectomy alone, but it was only the cause a neurologic deterioration in one patient. There was also a rare reported case of incarcerated spinal cord herniation with neurologic deterioration after laminectomy in a patient with OPLL and ossification of the ligamentum flavum (OLF).⁷⁵

Laminectomy with fusion (Figs. 44.6A to J) in patients with at least 10° of lordosis decreases the risk of postoperative kyphotic deformity and instability, but the functional improvement is similar to laminectomy alone or laminoplasty.⁷⁶ Anderson et al.⁷⁶ described several posterior cervical fusion techniques with lateral mass and pedicle screws and found that there is a low risk of neurovascular injury. Houten and Cooper⁷⁷ demonstrated that laminectomy and posterior lateral mass fusion can result in high rates of fusion, preserved lordosis, and clinical results comparable or superior to those seen with anterior

Figs. 44.6A to J: (A) Lateral radiograph of a patient with OPLL. (B) Axial CT demonstrating severe stenosis due to OPLL. (C) Sagittal MRI. (D and E) Flexion/extension radiographs demonstrating slight subluxation at C4/5. (F) Postoperative radiographs following laminectomy and posterior instrumentation. (G and H) Postoperative MRI following laminectomy and posterior instrumentation demonstrating increased space available for the spinal cord. (I and J) Postoperative flexion/extension radiographs.

cervical corpectomy and fusion. Hasegawa et al.⁷⁸ compared pedicle screw fixation with laminoplasty and reported higher operative times and more blood loss in the pedicle screw group. They concluded that the risk of vertebral artery or nerve injury was not justified with pedicular fixation in patients with standard OPLL. There is also description of spinous process wiring techniques for fusion reported by Epstein⁷⁹ that had 100% fusion rate and low complications. Obviously, this technique is difficult to perform following multilevel laminectomy.

Laminoplasty is a technique that has been around for many years and used for posterior decompression of the spinal canal in patients with cervical OPLL. There have been multiple techniques described. The benefits of this procedure, compared with laminectomy, are reduced risk of postoperative kyphotic deformity and a decrease in scar tissue around the cord, which can be associated with neurological deterioration.⁸⁰⁻⁸² There are, however, some limitations of laminoplasty including potential for the door closing,⁵³ axial neck pain, risk of OPLL progression, limited access to the hinged side in open-door laminoplasty, and

decreased effectiveness in cases with significant kyphotic deformity and large OPLL. The open-door laminoplasty technique has been modified to prevent closure by placing a spacer or bone graft at the site,⁸³ or by using a miniplate system to secure the opening.⁸⁴ There has also been report of rapid, unexpected OPLL progression with laminoplasty⁸⁵; therefore, adequate decompression proximally, distally, and transversely must be accomplished. The adequacy of spinal cord decompression after double-door laminoplasty was evaluated by Seichi et al.⁸⁶ using intraoperative ultrasonography. They found that an OPLL maximal thickness >7.2 mm was a cutoff value for insufficient decompression, but also found that neurological outcomes at 2 years did not correlate with adequacy of decompression.

The expansion ratio of the spinal canal and the increased inclination angle of the lamina two techniques was compared by Hirabayashi et al.⁸⁷ Open-door laminoplasty produced a significantly larger expansion ratio at C6 than double-door laminoplasty and the increase of inclination angle of the lamina was significantly larger in the double-door technique. They concluded that the surgical indications

for open-door laminoplasty included cervical spondylotic myelopathy (CSM) combined with hemilateral radiculopathy, large prominence of OPLL, and patients with a tiny spinous process who cannot undergo double door laminoplasty. The indications for double-door laminoplasty include CSM, small and slight prominence of OPLL, CSM combined with bilateral radiculopathy, and cervical canal stenosis combined with instability necessitating posterior spinal instrumentation surgery.

Long-term results with at least 5 years of follow-up of open-door laminoplasty showed recovery rates between 47.9% and 63.1%.⁸⁸⁻⁹² Expansive laminoplasty was shown to be a benefit even in patients with severe myelopathy.⁹³ All patients with symptoms <3 years, and 50% of patients with symptoms present from 3 to 6 years, improved after surgery. There are several factors that influence surgical outcomes following laminoplasty. Worse outcomes are associated with duration of myelopathy,^{89,93,94} severity of myelopathy,⁹⁰⁻⁹² age,⁸⁹⁻⁹¹ preoperative kyphosis,⁸⁸ occupying ratio >60%,⁹¹ and hill-shaped ossification.⁹¹ Neurological function was found to be significantly improved after surgery, maintained for 5 years, and slightly decreased after 5 years.^{88,95} Ogawa et al.⁹⁵ also found that the degree of deterioration correlated with cervical range of motion. This motion is decreased by approximately

32%^{96,97} after laminoplasty and plateaus by 18 months after surgery.⁹⁶ C5 nerve root palsy after laminoplasty or laminectomy has been a concern. Sakaura et al.⁹⁸ found the incidence of postoperative C5 palsy to be 4.6%. It is believed to be due to a tethering effect versus local ischemia of the C5 nerve root after posterior drift of the cervical spinal cord after decompression.^{99,100} Selective C5 foraminotomies can be performed in an effort to relieve tension on the C5 nerve root; however, patients with C5 palsy generally have a good prognosis for functional recovery.¹⁰¹

Anterior Approaches

Anterior approaches are all variations of corpectomies or discectomies with or without fusion. Procedures include ACDF, anterior cervical corpectomy and fusion (ACCF),¹⁰² open-window corpectomy, oblique corpectomy (the ventral half of the body is preserved), skip corpectomy, and anterior corpectomy with floating technique. Neurologic improvement rates for the various techniques range from 51% to 71.7%. Even in poor-grade patients (Nurick grades 4 and 5), Rajshekar and Kumar¹⁰³ showed that corpectomies led to neurologic improvement in 76% of patients. Anterior cervical discectomy and fusion (Figs. 44.7A to C) is a very useful procedure in the treatment of OPLL. Koyanagi et al.⁶⁸ reported a high incidence of associated disc

Figs. 44.7A to C: T2 magnetic resonance imaging, computerized tomography scan, and postoperative plain radiograph (A to C) depicting segmental ossification of the posterior longitudinal ligament treated with anterior corpectomy and fusion.

herniation in patients with cervical OPLL, and found that disc herniation was present at the level of maximal compression in 60% of patients. This is the procedure of choice for circumscribed-type OPLL; however, it is not indicated in multilevel, continuous-type OPLL. The recovery rate with ACDF ranges from 51% to 63.2%.^{104,105} There has also been report on endoscopic ACDF by Tan et al.¹⁰⁶ with good results, but it can only be used at C4-C5 and C5-C6 levels.

Long-term follow-up (mean 14.7 years) of anterior interbody fusion without decompression was investigated by Onari et al.¹⁰⁷ in patients with cervical OPLL. Twenty four of 30 patients improved after surgery and the procedure was more effective for patients with the segmental and circumscribed type. This study indicated that a dynamic factor is an important contributor to myelopathy in patients with cervical OPLL.

The open-window corpectomy technique has been described and creates a more stable construct with three-point fixation and better load sharing between implants and healthy vertebrae. The open-window corpectomy technique is designed to remove a minimal amount of bone and achieve satisfactory decompression. With the use of a high-speed drill under a surgical microscope, only the dorsal surface of the corpus is removed after appropriate microdissectomies. This leaves the anterior and the lateral portions of the vertebral corpus intact. The technique was used by Ozer et al.¹⁰⁸ and reported satisfactory outcomes.

Oblique corpectomy is a technique that preserves the ventral half of the vertebral body so fusion and stabilization is not required. Two case series, one by Goel and Pareikh¹⁰⁹ and the other by Chacko and Daniel,¹¹⁰ both used this technique with clinical success.

The skip corpectomy technique involves nonadjacent level corpectomies with preservation of the intermediate vertebral body. Dalbayrak et al.¹¹¹ performed this technique in 29 patients with multilevel CSM and OPLL. The mean JOA score improved from 13.44 to 16.16 after surgery. There was only one complication with C7 screw pullout; overall they found that retention of the intermediate vertebral body fixation strengthened the construct. The floating method with anterior corpectomy and fusion described by Yamaura et al.¹¹² involves floating the OPLL segment after the corpectomy. This procedure causes decompression of the spinal cord and restores its function by enlarging the neural canal with anterior migration of the ossified ligament. The procedure minimizes the extent of surgical invasions and avoids damage to the neural tissue, because it does not require the removal of the OPLL. It also may

prevent postoperative regrowth of the ossification. Sakai et al.¹¹³ performed a 5-year prospective study comparing the anterior floating method to laminoplasty. They showed that the floating method has acceptable outcomes and is suitable for patients with massive OPLL and preoperative kyphosis, although there is a higher rate of surgical complications with the floating method compared to laminoplasty.

Surgical Decision Making for Cervical OPLL

There is no consensus for optimal surgical technique for cervical OPLL. Numerous factors should be taken into consideration on a case-by-case basis to decide the best approach: number of levels involved, amount of kyphosis of the cervical spine, whether the OPLL lesion occupies >60% of the spinal canal, and type of OPLL. In order for a posterior procedure to be effective, there must be at least some lordosis to allow the spinal cord to drift posteriorly away from the OPLL lesion. Also, large OPLL (> 60% of spinal canal) has better outcomes with decompression anteriorly.¹¹³ Continuous-type may be better dealt with using a posterior approach, whereas isolated segmental- or circumscribed type may be better handled with an anterior approach. Large continuous lesions may be better served with multilevel anterior corpectomy and posterior spinal fusion for further stabilization (Figs. 44.8A and B). The

Figs. 44.8A and B: Postoperative radiographs of an anterior corpectomy with fusion and posterior fusion for a large, continuous ossification of the posterior longitudinal ligament. Shows anterior and posterior instrumentation C3-C7.

advantages and disadvantages of surgical procedures for cervical OPLL are displayed in Table 44.2.

SURGICAL TREATMENT OF THORACIC OPLL

The outcomes after surgical treatment of thoracic OPLL are poorer than the results after cervical OPLL. There are several reasons for the limited effectiveness of decompression in the thoracic spine.^{114,115} The first factor is the natural kyphosis of the thoracic spine that restricts the backward shift of the spinal cord away from the OPLL with posterior decompression. The second factor is that the thoracic spinal cord is relatively avascular and more vulnerable to ischemic injury during surgical manipulation. Lastly, the ribcage restricts surgical approaches to the spine.

Surgical options for thoracic OPLL include posterior laminectomy or laminoplasty, posterior decompression and fusion, anterior transthoracic decompression, circumspinal decompression posteriorly with costotransversectomy, and two-stage anterior and posterior decompression.¹¹⁶ The simplest method is posterior decompressive laminectomy alone; however, this technique disrupts the posterior tension band of the thoracic spine and may lead to instability and neurologic deterioration. There have been reports of laminectomy in patients with thoracic OPLL that suffered postoperative neurologic deterioration.^{117,118} These two patients underwent reoperation with instrumented fusion and both gradually improved neurologically. Nakanishi et al.¹¹⁹ redemonstrated the importance of fusion after laminectomy after seeing a decrease in evoked potentials after laminectomy with subsequent return of amplitude after posterior instrumented fusion. Matsumoto et al.¹²⁰ also recommended posterior instrumented fusion after looking at factors related to outcomes after thoracic OPLL surgery. The above studies emphasize the importance of a dynamic factor with progression of kyphosis as the cause of neurological deterioration after laminectomy alone. There are two descriptions of thoracic OPLL: beak type and flat type. Flat type is analogous to low profile continuous type in the cervical spine. There are no sharp or large protrusions. Beak type has more of a large, sharp protrusion on sagittal view that resembles the beak of a bird. Beak type has a higher risk of neurological deterioration after posterior decompression.¹²¹

Thoracic laminoplasty was evaluated by Komagata et al.¹²² and Matsumoto et al.¹²⁰ Both studies showed the effectiveness of laminoplasty; however, it is safer to only use

it at the nonkyphotic upper thoracic spine (T1-T4) as there were two cases of transient leg paralysis in the mid-to-lower thoracic spine.

Posterior decompression with fusion generally has a lower complication rate compared with posterior decompression alone and anterior approaches. Yamazaki et al.¹²³ performed one of three approaches on patients with thoracic OPLL: posterior decompression alone, posterior decompression and fusion, and anterior approach with extirpation. Decompression alone had the highest complication rate followed by anterior extirpation. The fusion group had no cases of postoperative paralysis or late neurological deterioration. Due to the thoracic kyphosis, the ability of decompression and fusion to effectively improve neurologic function has been questioned. Yamazaki et al.¹²⁴ followed patients for over 4 years after posterior decompression and in situ fusion. There was only a 58.1% recovery rate and the median time to maximal recovery was 9 months.

Posterior decompression with kyphosis correction has also been studied with a recovery rate ranging from 56% to 68%.^{125,126} Zhang et al.¹²⁶ performed posterior decompression and fusion with 5°–15° of kyphosis correction. Postoperative MRI showed backward shift of the spinal cord and complete decompression in all cases.

Tokuhashi et al.¹²⁷ determined that the critical ossification-kyphosis angle that affects outcome in patients who underwent posterior thoracic decompression is 23°. All patients with an angle >23° had no echo-free space detected by intraoperative ultrasound, whereas all patients with <23° had echo-free space.

The anterior approach alone for thoracic OPLL is technically demanding and has poor surgical results, especially in patients who already have severe spinal cord compression. Min et al.¹²⁸ reported high complication rates with anterior decompression in 19 patients with thoracic OPLL. Two patients developed neurological deterioration and six patients developed CSF leakage.

The circumspinal decompression from a posterior only approach has the benefit of anterior and posterior decompression and stabilization with only one surgical approach. Yang et al.¹²⁹ reported satisfactory outcomes using this technique for T10-T11 OPLL. Takahata et al.¹¹⁶ reported on a series of 30 patients with this technique followed for 8 years. The JOA score improved in 24 patients; however, there were significant complications, including 40% with dural tears, 10% with deep infections, and 33%

Table 44.3: Summary of advantages and disadvantages for thoracic OPLL surgery.

<i>Surgical procedure</i>	<i>Advantages</i>	<i>Disadvantages</i>
Post decompression	Simple, less operating time and blood loss	High risk for Postop paralysis and late neurological deterioration
Post decompression w/fusion	Less operating time and blood loss compared w/Ant or combined approach, low risk of Postop paralysis	Persistent Ant impingement of spinal cord by OPLL
Ant decompression through Ant approach	Direct removal of OPLL	High risk for Postop paralysis and CSF leakage, technically demanding, more operating time and blood loss
Circumspinal decompression through Post approach	Immediate Ant and Post decompression and stabilization w/only 1 operation	Technically demanding, more operating time and blood loss
2-stage Post, Ant decompression	Complete Ant and Post decompression	Technically demanding, more op time and blood loss

(OPLL: Ossification of the posterior longitudinal ligament, Ant: Anterior; Post: Posterior; Postop: Postoperative).

with postoperative neurological deterioration. Patients with decompression of five or more levels had worse outcomes. Other reports by Hioki et al.¹³⁰ and Kawahara et al.¹³¹ described circumspinal decompressive techniques, which generally had improvements with surgery; however, both had significant complications including dural tears and neurological deterioration.

Surgical Decision Making for Thoracic OPLL

The surgical outcomes of patients with thoracic myelopathy are correlated with preoperative duration of symptoms and the degree of myelopathy. Patients with shorter duration of symptoms and milder myelopathy experienced the best surgical outcomes.²³ There is still no consensus or definitive guidelines for the surgical treatment of thoracic OPLL. Numerous factors should be taken into consideration when deciding to operate on symptomatic thoracic OPLL: number of levels and type of OPLL, amount of cord compression, and the experience of the surgeon. Generally, most studies indicate that posterior decompression and fusion with or without mild kyphosis correction will provide adequate surgical outcomes with the least risk of complications. However, with very severe compression, there is a role for posterior decompression and fusion with subsequent anterior decompression. The advantages and disadvantages of surgical procedures for thoracic OPLL are summarized in Table 44.3.

SURGICAL MANAGEMENT OF LUMBAR OPLL

Symptomatic lumbar OPLL is much rarer but does exist and usually is located in the upper lumbar spine where the posterior longitudinal ligament is much broader. Patients may present with cauda equina syndrome and most are approached posteriorly with decompression. Tamura et al.¹³² described two cases of lumbar OPLL: one treated with an anterior approach and the other with an anteroposterior approach. They recommended combined anterior-posterior surgery in patients with OPLL occupying a large part of the spinal canal.

SURGICAL COMPLICATIONS

Although most complications were discussed in the above sections, Li et al.¹³³ performed a systematic review of complications in cervical OPLL surgery. The authors found that the main complications to be cerebrospinal fluid leakage (CSF), neurologic deficit including motor weakness or palsy, such as C5 palsy and sensory disturbances, axial neck pain, implant complications, nonunion, hoarseness, dysphagia, dyspnea, and hematoma. Anterior approach surgery has a higher incidence of CSF leak, implant complications, and hoarseness, dysphagia, and dyspnea. Posterior approach is most commonly associated with axial neck pain and C5 palsy. Other neurologic deficits were seen with both approaches and were found to be the most common complication in cervical OPLL surgery. Most deficits completely resolved spontaneously but recovery time varied from 1 week to 2 years.

CONCLUSION

Ossification of the posterior longitudinal ligament is a disease predominantly found in people of Asian descent but is found to a lesser extent across the globe. The exact etiology is not fully elucidated, but there is a strong genetic component with multiple genes currently being studied as major contributors to the disease. There is also believed to be a dynamic, mechanical component that leads to the myelopathy seen in the disease. The natural history shows that people that present without myelopathy are unlikely to progress and prophylactic surgery is not needed. Patients with myelopathy generally will require surgical intervention to prevent progression of symptoms. There are four types of OPLL, and they all can be evaluated with various diagnostic studies including plain radiography, CT scan, and MRI. Surgical treatment of OPLL should be considered on a case-by-case basis. There is no consensus or standard treatment for OPLL, but general guidelines can help direct the approach. Patients with kyphosis, lesions occupying >60% of the canal, and segmental-type OPLL have better outcomes with an anterior approach. Smaller, continuous lesions with no kyphosis are better served with a posterior approach. Patients with thoracic OPLL have poorer outcomes than cervical OPLL in general, but adequate recovery can be obtained with posterior decompression and fusion with possible anterior decompression. Complications can occur with all approaches, but overall have acceptable rates and generally favorable prognosis.

KEY POINTS

- Ossification of the posterior longitudinal ligament predominantly affects people of Asian descent, but can be found around the globe.
- The etiology of OPLL is not fully elucidated; however, there is a strong genetic and mechanical component leading to the formation and progression of the disease.
- The natural history shows that patients that present without myelopathy are unlikely to progress; however, patients with progressive myelopathy will need surgical intervention to halt the progression.
- There are four types of OPLL: continuous, segmental, mixed, and circumscribed. They are best evaluated with CT scan for the bony lesion and MRI for the impact on the spinal cord.

- There are multiple surgical approaches for OPLL with no general consensus as to the best approach. Anterior approaches are most favorable for lesions >60% of the spinal canal diameter, segmental type, and when there is kyphosis present. Posterior approaches are better suited for continuous-type, smaller lesions with no kyphotic deformity.
- Complications occur with all approaches. Dural tears, hardware issues, and dysphagia are most common with anterior surgery, and axial neck pain and nerve palsies (C5) are more common with posterior surgery.

INTRODUCTION

Methods for fusing the occipitocervical and atlantoaxial spine have evolved significantly with changes in instrumentation techniques. Historically, C1-C2 fusion techniques involved the use of corticocancellous autografts or allografts and wires, as per the Gallie, Brooks-Jenkins, and the Sonntag techniques. Methods for occipital fixation involved expansions on the use of the corticocancellous bone grafts to involve the occiput, using burr holes in the occiput to thread wires through for fixation. This was a technique first described and used by Drummond and Dormans in 1995 and subsequently modified by the use of structural rib allograft described in 2001.^{1,2} However, with the modernization of instrumentation, fixation techniques evolved away from wiring, to plate and screw fixation, to what is now predominantly a skull plate attached by rods to screws in the spine.

The transition from a predominant wire-based fixation to screw and rod fixation started with Magerl and Seeman in 1987, where a posterior transarticular screw combined with posterior wiring was used to provide more rigid fixation from traditional techniques. Percutaneous techniques have been described by Dickman et al. and McGuire et al. in 1995.³⁻⁵ However, biomechanical studies started to provide objective evidence of superior fixation provided by screw fixation over wires, setting the stage for the

transition to all screw/rod constructs.⁶ Goel, and later, Harms, described the technique for C1-C2 arthrodesis with an all screw construct.^{7,8} Anterior C1-C2 transarticular screws, described by Lu, is yet another method of C1-C2 fixation, although not as popular as the other methods.⁹

This chapter reviews modern techniques used in O-C and C1-C2 fusions with a bias toward those techniques utilized by the senior author K.D.R. A specific focus is placed on the technical aspects of the operative techniques utilized.

SURGICAL APPROACH: ANATOMIC AND TECHNICAL CONSIDERATIONS

The surgical approach for screw and rod fixation involves a more thorough knowledge of the normal anatomy as well as its variations or anomalies and often, a wider surgical dissection when compared to historical techniques such as the Gallie fusion. Specific anatomic considerations include the vertebral arteries, the C2 dorsal root ganglion and greater occipital nerve, the C1-C2 venous plexus posteriorly and the internal carotid artery, hypoglossal, glossopharyngeal and superior laryngeal nerve anteriorly.

Posterior Upper Cervical

The exposure of the upper cervical spine involves an incision that extends from the base of the occiput to the

Figs. 45.1A and B: (A) Coronal view of the C1 vertebrae and its relationship to the vertebral artery. (B) Notice on this sagittal view, the position of the vertebral artery, ventral to the C1 lamina.

spinous process of C2. When the fusion is limited to C2 and above, the insertion of the fibers of the semispinalis cervicis on the dorsolateral and caudal aspect of the C2 spinous process must be preserved because this muscle is the main extensor of cervical spine and its detachment may cause neck pain, kyphosis, and limitation of motion. This is especially important for C1-C2 fusions that do not involve fixation of more distal levels.

The typical course of the vertebral artery after it comes through the transverse foramen at C1 is to course medially and dorsally. This places the artery on the cranial edge of the lateral aspect of the C1 lamina before it enters the foramen magnum. Exposure of the C1 lamina farther than 1.5–2 cm from midline places the vertebral artery at risk for injury. Just caudal to the lamina, however, we routinely dissect 2–3 cm lateral to the midline, in order to expose the ideal starting point for a C1 lateral mass or posterior arch screw. We use a broad Cobb elevator to very gently dissect the muscles off of the posterior arch of C1 and have found this to be a safe technique, as the artery usually lies ventral to the arch (Figs. 45.1A and B). Usually, the superior aspect of the artery is not bordered by bone, while the inferior edge sits on the C1 lamina; however, sometimes, the artery is completely encased within bone superiorly, and this rostral osseous edge is called the *ponticulus posticus*¹⁰ (Figs. 45.2A and B). This can easily be identified on a lateral radiograph. Magnetic resonance imaging (MRI) or computerized tomography (CT) angiogram can be useful to rule out vertebral artery aberrancies such as high riding vertebral artery and vertebral artery anomalies such as fenestration and persistent first intersegmental artery. At the very least, a preoperative CT is absolutely mandatory to check for a

high riding or aberrant vertebral artery course, as well as bony dimensions that may preclude the use of transarticular, pedicle, or pars screws.

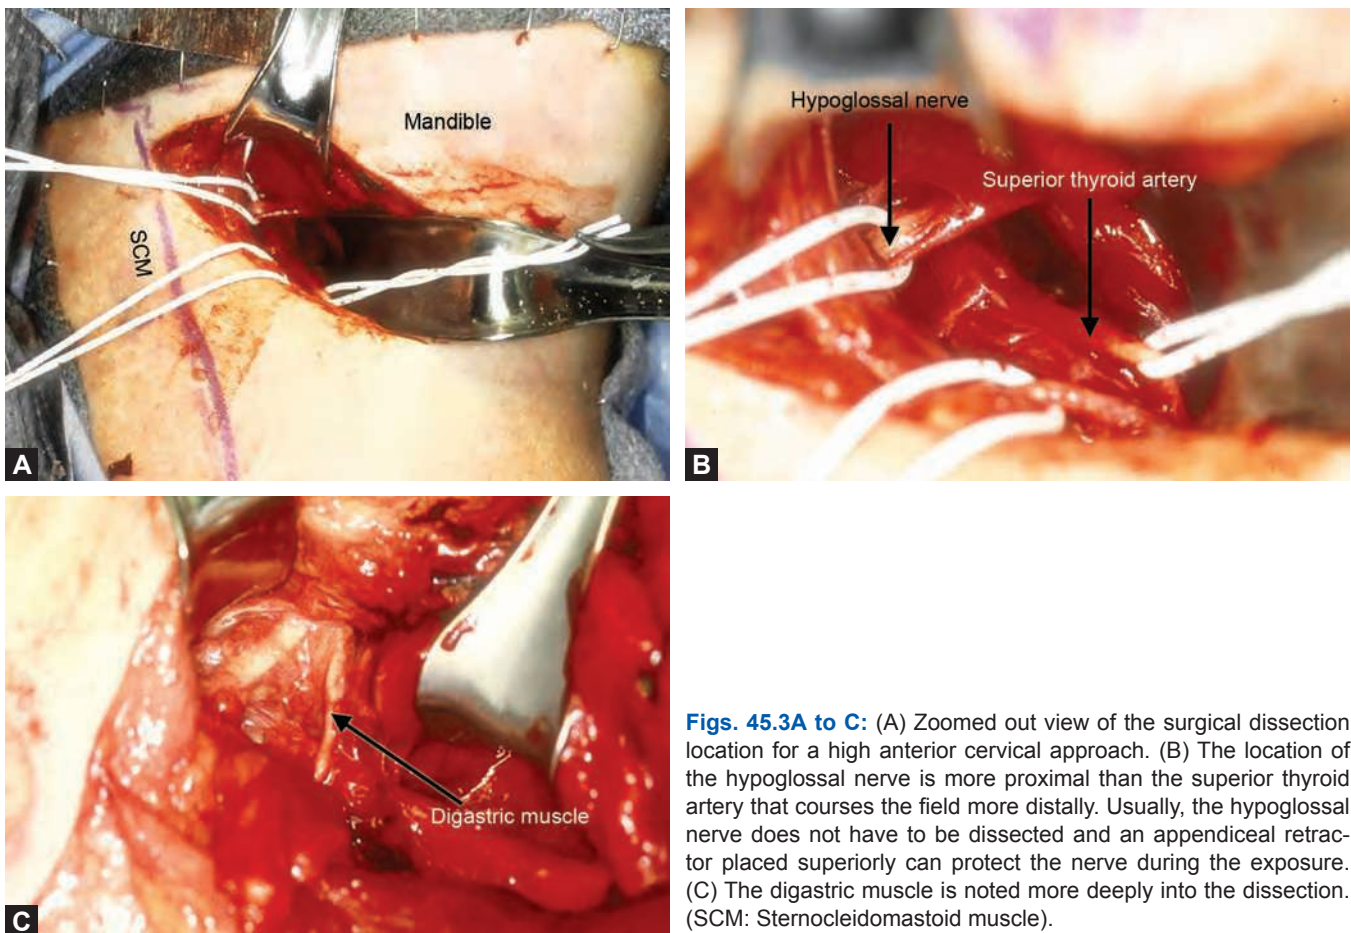

During deep dissection of C1 and C2 near the C1-C2 facet joint, a slow and careful subperiosteal dissection with the use of a Penfield 4 retractor may be helpful to avoid injury to the venous plexus and the C2 nerve root and its dorsal ganglion. Excess bleeding is controlled with a combination of bipolar electrocautery, liquefied collagen or collagen sponges with thrombin, surgicel, and pressure with patties.

Anterior Upper Cervical

The anterior approach to the upper cervical spine may be performed through a Smith–Robinson approach. One needs to dissect posterior and superior to the angle of the jaw and the submandibular gland. Bohlman and McAfee described this approach for exposing the upper cervical spine.¹¹ While interesting, we find this description to be overly complex. By using careful, mostly blunt dissection with scissors, under the microscope, and not cutting any nerves crossing the field, we have exposed countless cases up to C2 and only bother to look for the nerves that cross the field out of academic interest. Some important neurologic structures that are typically not seen are the superior laryngeal nerve, which usually crosses the field at about the C3–C4 region. It usually runs with the superior thyroid artery and vein. The glossopharyngeal nerve is found more cranial and crosses deep to the external carotid artery (Figs. 45.3A to C). It is close to the digastric muscle and is typically much thicker than the superior laryngeal nerve.

Figs. 45.2A and B: (A) A lateral radiograph demonstrating a ponticulus posticus with the (B) corresponding computerized tomography reconstruction; notice the relationship of where the vertebral artery (VA) courses in relation to the C1 lamina and the ponticulus posticus.

Figs. 45.3A to C: (A) Zoomed out view of the surgical dissection location for a high anterior cervical approach. (B) The location of the hypoglossal nerve is more proximal than the superior thyroid artery that courses the field more distally. Usually, the hypoglossal nerve does not have to be dissected and an appendiceal retractor placed superiorly can protect the nerve during the exposure. (C) The digastric muscle is noted more deeply into the dissection. (SCM: Sternocleidomastoid muscle).

The hypoglossal nerve is usually more superficial as it crosses over the external carotid artery before diving deep to the stylohyoid and mylohyoid muscles. Careful blunt

dissection will protect the structures from iatrogenic injury. Small crossing vessels can be clamped with a hemostat and then coagulated with bipolar cautery to

physically and thermally occlude the lumen, obviating the need for clips or suture ligation.

■ INDICATIONS FOR SURGERY

There are a variety of indications for surgical intervention at the occipitocervical and atlantoaxial joints. Generally speaking, surgery is indicated if a condition causes severe instability, severe local pain including that caused by arthritis or destruction of the facet joints, or neurologic compromise including myelopathy as well as C2 root compression causing intractable occipital neuralgia. These conditions can be broken into broad categories of degenerative, developmental, congenital, inflammatory, infectious, traumatic, and neoplastic etiologies. A discussion into the specifics of the cause for instability, pain, or neurologic compromise from these conditions is beyond the scope of this chapter but should nevertheless be understood and recognized by spine surgeons.

■ ATLANTOAXIAL FIXATION OPTIONS

The authors' preferred technique for C1-C2 arthrodesis is the C1 lateral mass screw and C2 pedicle screw fixation. The advantages of this technique over others such as transarticular fixation are many. First, the fixation of C1 and C2 individually allows for reduction of any subluxations after instrumentation during rod assembly.¹² This is in contrast to transarticular screws where one has to reduce first and then instrument while holding the reduction. Second, placement of pedicle screws at C2 allows for less of a dissection than the C2 pars screw, which has a more distal and medial starting point. Lastly, the placement of C1 lateral mass screws and C2 pedicle screws does not need fluoroscopic guidance as opposed to the placement of transarticular screws.¹³ As stated above, a preoperative CT is necessary to determine if the C2 pedicles are large enough to accept a screw. A high riding or medial vertebral artery will preclude the possibility of a pedicle screw (Figs. 45.4A to C). In such cases, one can use a pars or a C2 laminar screw, described by Wright.¹⁴

Anterior C1-C2 Transarticular Screw Fixation

Lu et al. described the anatomic parameters for the placement of anterior C1-C2 transarticular screw fixation.⁹ They concluded that anterior transarticular screws, which uses a starting point at the concavity on the anterior cortex of

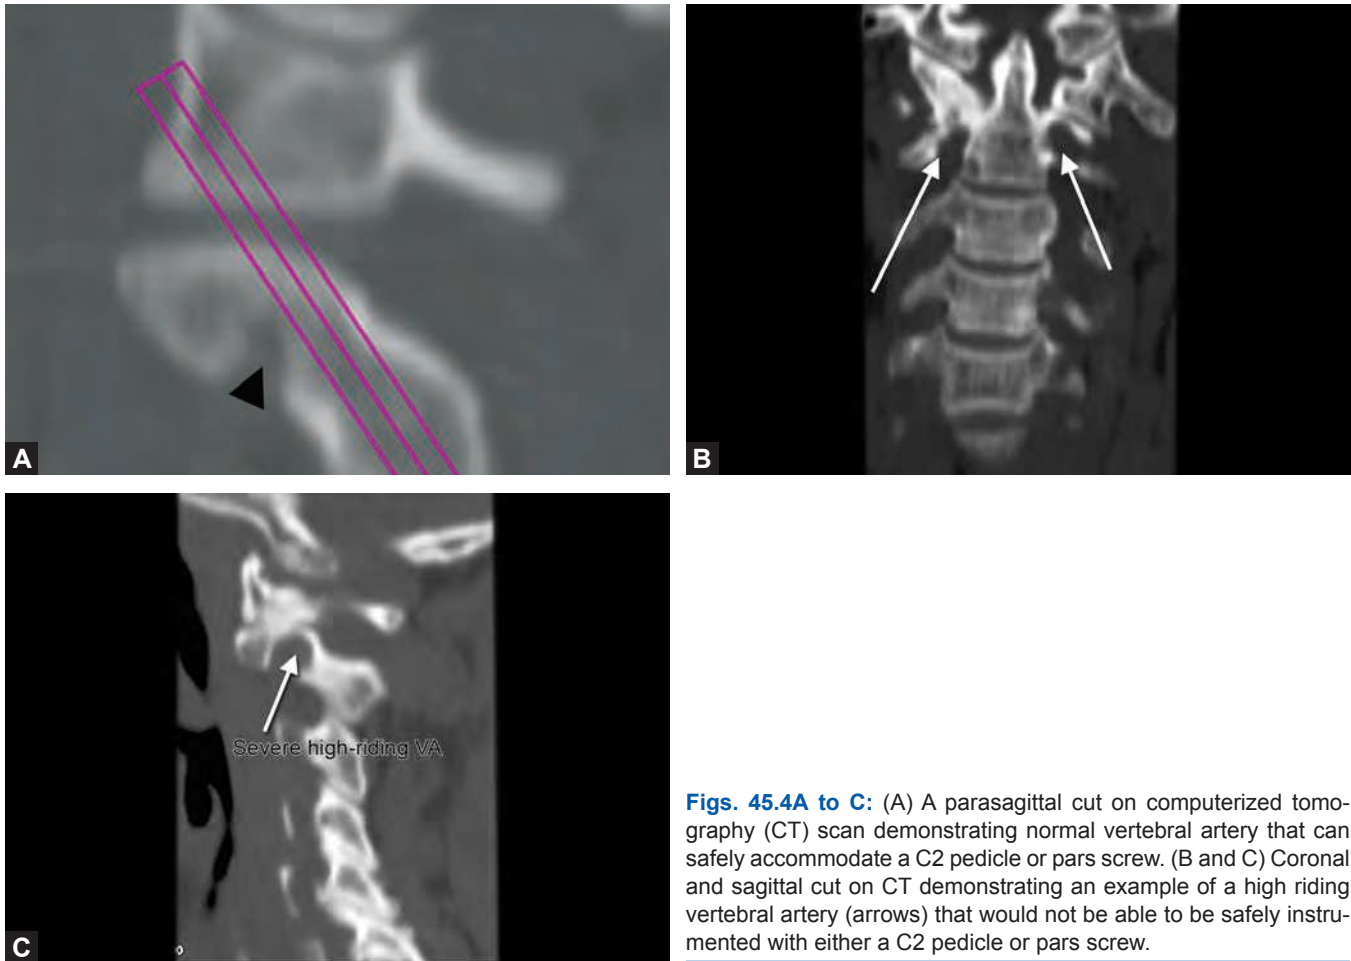

the C2 arch, should be angled 20° laterally and 20° posteriorly to be placed safely. With this method, a screw length of 15–20 mm is usually sufficient.⁹

More recently, percutaneous methods for anterior transarticular screw placement have been described.^{15,16} This technique uses a starting point at the anterior inferior endplate of the C2 vertebral body with a trajectory that is aimed 20–30° lateral and 20–28° posteriorly. With this method, a screw length of 40–50 mm can be achieved.

There are several challenges to placing anterior transarticular screws. These include the potential damage to the superior laryngeal nerve as well as problems with dysphagia that are associated with an anterior procedure. In addition, the mandible makes it difficult with even open anterior approaches to adequately decorticate and bone-graft the C1-C2 joints bilaterally. A transoral decortication and grafting may be necessary. Lastly, the trajectories of the anterior screws are directed from medial to lateral. This means that while the contralateral screw might be easier to place, screw placement for the ipsilateral side of the approach will require extensive retraction of the midline structures past midline.¹² Nonetheless, this approach is a useful adjunct to a cervical spine surgeons' armamentarium because certain circumstances make this a better option for fixation (i.e. abnormal vertebral artery course or the absence of posterior osseous structures due to prior surgery).

■ TRANSORAL ATLANTOAXIAL REDUCTION PLATE

Since being described in the literature in 2005,¹⁷ the transoral atlantoaxial reduction plate has been indicated for an irreducible atlantoaxial dislocation due to basilar invagination, Arnold-Chiari malformation, congenital odontoid dysplasia, free dens, rheumatoid arthritis, old odontoid fractures, and old C1 transverse ligament disruption.¹⁸ This technique necessitates the anatomic structure of the C1 lateral masses and C2 vertebral body to be intact. Recently, this technique was used to treat a posterior atlantoaxial dislocation.¹⁸ The authors from this report have performed over 160 cases of C1-C2 fusions utilizing this technique for anterior atlantoaxial dislocations with good clinical results (Figs. 45.5A to D). The advantage of utilizing this technique is that a reduction, decompression, fixation, and fusion can all be achieved by a one-staged operation. Traditionally, the transoral approach has been utilized for odontoid excisions without fusion.

Figs. 45.4A to C: (A) A parasagittal cut on computerized tomography (CT) scan demonstrating normal vertebral artery that can safely accommodate a C2 pedicle or pars screw. (B and C) Coronal and sagittal cut on CT demonstrating an example of a high riding vertebral artery (arrows) that would not be able to be safely instrumented with either a C2 pedicle or pars screw.

Posterior Magerl Transarticular Screw

The posterior transarticular technique was first described by Magerl and Seeman and is an excellent method for providing rigid C1-C2 fixation.³ Biomechanical studies of transarticular screws have shown excellent stability except in flexion and extension.⁴ This can usually be addressed by supplementing the construct with wiring of the spinous processes of C1 and C2.

Much like any technique for instrumentation of C1 and C2, extensive preoperative imaging including plain radiographs, MRI, and CT are essential for operative planning. Sagittal and parasagittal reformatted images are critical to evaluating the location of the vertebral arteries to determine the feasibility of this technique. Sometimes, the C2 pars may be too thin or the position of the vertebral artery too medial or dorsal to allow for the use of the Magerl technique. It is estimated that up to 20% of cases exhibit anatomic limitations for using the transarticular screw, so in no way are these anatomic variations a rarity.¹⁹⁻²¹

The starting point of the C1-C2 Magerl screw is approximately 3 mm proximal to the C2-C3 facet joint line and 3 mm lateral to the medial border of the lateral mass. The trajectory in the sagittal plane of the screw will vary based on the location of the anterior tubercle of C1; however, in the coronal plane, we usually aim 0–5° medially. If there is a subluxation of C1 on C2, using any part of the C1 anterior tubercle is not recommended because the position of the C1 anterior tubercle is determined by the degree of subluxation. Instead, the screw trajectory needs to be directed as dorsally as possible in order to minimize the possibility of violating the anteriorly located C2 vertebral artery groove²²⁻²⁴ (Fig. 45.6). The amount of medial angulation depends on the location and course of the vertebral artery at the level of the C2 pars. Whenever possible, we believe that it is much better to place the screw only after reducing the C1-C2 joint first. This can be done sometimes by retracting (translating the neck posteriorly) and extending the neck. Too much extension, however, can make the screw trajectory impossible, so this should be checked prior to

Figs. 45.5A to D: (A) Lateral radiographs, (B) with corresponding magnetic resonance imaging, (C and D) status post-transoral atlantoaxial reduction plating demonstrating anatomic reduction, decompression, and restoration of the space available for the cord at C1. *Courtesy:* Dr Qingshui Yin, Department of Orthopaedics, Guangzhou General Hospital of Guangzhou Military Region, Guangzhou, Guangdong, PR, China.

Fig. 45.6: In order to avoid possible violation of the C2 vertebral artery groove during posterior transarticular C1-C2 screw placement, the screw trajectory needs to be as dorsally directed as possible.

the prep and drape under fluoroscopy. Intraoperatively, one can place a cable under the arch of C1 and caudal to the spinous process of C2, underneath the still attached semispinalis cervicis. By tensioning the cable, the C1 ring is pulled posteriorly. If the patient has severe cord compression at the C1 level, it is sometimes possible to pull the arch posteriorly first with a Kocher or tenaculum, so as to create more space for the cord, prior to placing the cable. If this is not possible, then one should not attempt to place a cable underneath the arch of C1, as it can cause cord injury.

Under fluoroscopy, the screw tip should be directed toward the bottom half of the anterior tubercle of C1. It should stop short of the posterior cortex of the tubercle, since a longer screw will protrude into the soft tissues, placing the internal carotid artery at risk in some individuals.

The risk of vertebral artery injury with this technique is estimated to be 4.1%.¹⁴ If the artery is injured, one should place a short screw to tamponade the bleeding. With a minor injury, the artery may be able to repair itself in time. If a long screw is placed through the artery, however, it has no chance of reconstituting itself. Postoperatively, angiographic studies should be obtained to assess the injury. Most importantly, placement of a screw on the contralateral side should not be attempted, since bilateral vertebral artery injury usually results in severe neurologic deficit or death.

C1-C2 Segmental Screw Fixation

The technique for utilizing C1-C2 segmental fixation was first described by Goel with the use of screws and plates in 1994 and then by Harms and Melcher with the use of screws and rods in 2001.^{7,8} This is our preferred technique. We describe the method we use for screw fixation of the C1 lateral mass as well as C2 pedicle and review methods for salvaging fixation points in C2.

With this approach, patients are positioned prone on an Orthopedic Systems, Inc. (OSI) frame with traction placed at 15 lb through Gardner-Wells tongs. The surgical approach is that which was described in the earlier part of this text for the posterior upper cervical approach.

C1 Lateral Mass Screw

The inferior border of C1 may be delineated with electrocautery. However, care is used for the superior border, since injury to the vertebral artery can occur. A Penfield 4 or 2 is used to subperiosteally dissect the C2 ganglion and venous plexus off of the arch. Keeping the dissection completely subperiosteal is a key to avoid unnecessary bleeding from the venous sinuses.

The C2 nerve root and its dorsal root ganglion, which supplies the greater occipital nerve, is between the C1 posterior arch and C2 pars and posterior to the C1-C2 facet joint, and care is taken to use a Penfield to gently retract the nerve distally toward the C2 lamina. A large venous plexus lies just cranial, lateral and deep the C2 nerve root and care should be taken not to manipulate this area too much unless a decision is made to sacrifice the C2 nerve root, in which case aggressive bipolar cautery can be used to cauterize the venous plexus. We usually preserve the C2 nerve root and therefore use thrombin-based hemostatic agents, surgical, and mechanical pressure by way of a cottonoids to control the bleeding. Again, keeping the dissection plane strictly subperiosteal is a key to minimize

bleeding. While some have recommended routinely sacrificing the C2 nerve, a recent study found that doing so can result in disabling pain in some patients.^{25,26}

Prior to instrumentation of the C1 lateral mass, the C1-C2 articulation is decorticated with the use of a burr, while the C2 nerve root is retracted cranially, and fresh frozen allograft bone is placed along with the bone dust from the decorticated joint (see Figs. 45.5A to D). When decorticating, be aware of how close the artery is to the subchondral bone at C2 by examining the CT scan. Screw placement can now commence. Whenever possible, we utilize a C1 arch screw, as this requires less of a soft tissue dissection than a lateral mass screw.²⁶ In addition, the screw has purchase in more bone with this technique. If a lateral mass screw is necessary, we first use a Penfield 4 to identify the medial and lateral borders of the C1 lateral mass. Midway between the medial and lateral borders is the starting point for our screw.

We then notch the inferior aspect of the C1 posterior arch with a burr to create a space into which the screw will be recessed¹³ (Figs. 45.7A to D). This recess allows a more caudally directed screw trajectory because the overhang of the C1 posterior arch is eliminated. Another advantage of the notch recess is that the tulip of the screw head can also sit more cranially when the screw is inserted so that the screw heads are not too crowded after placement. Nevertheless, this step is only performed, if and only if the corresponding sagittal cuts on the CT scan as well as the MRI show that the vertebral artery would not be compromised with such a maneuver. If there is a risk for vertebral artery injury, we usually dissect the artery off of the cranial aspect of C1 and protect it with a cottonoid prior to forming the recess.¹³

The Penfield retractor then moves distally to protect the C2 nerve root. A cottonoid can be used to cushion the nerve root, so direct pressure from the Penfield is not applied to the nerve root. A drill is then placed into the recess that was burred until a bony endpoint is reached. We aim the C1 lateral mass screw 0–5° medially.^{13,27} Care is taken not to aim too cranially, since this can result in screw threads violating the O-C1 articulation. By aiming the screw as close as possible toward the C1-C2 joint without violating it, one can avoid this complication.

A radiographic and anatomic analysis on the optimal screw trajectory to prevent this occurrence concluded that a trajectory below the 40% mark of the anterior arch of the atlas on a radiograph was the safe zone for C1 lateral mass screw placement.²⁷ There are certain anatomic

Figs. 45.7A to D: (A) Recessing the inferior margin of the C2 lamina allows for a more caudally directed trajectory of the C2 lateral mass screw in order to avoid violation of the occipitocervical joint. (B) This can be safely performed by confirming the position of the vertebral artery. (C) Once tapped and the screw is placed (D), you can see that the tulip of the screw head is located more cranially which also prevents impingement of the C2 nerve root that typically courses just distal to this screw head.

Figs. 45.8A and B: (A) Coronal and (B) sagittal anatomic specimens of the C2 anatomy demonstrating the more lateral and cranial starting point for the C2 pedicle screw (*) in comparison to the C2 pars screw.

nuances that must be taken into consideration with this value. Specifically, the anatomy of C1 lateral mass is shaped like a bow tie on a coronal view. Therefore, the O-C1 articulation extends more caudally at its medial aspect (see Figs. 45.1A and B). Therefore, C1 screw starting points should not be too medial, since this will decrease the amount of room available in the safe zone. In other words, more medial starting points will have a safe zone of 20% of the height of the anterior arch of C1, while more lateral starting point screws will demonstrate a safe zone up to 40% in order to avoid violation of the O-C1 joint.²⁷

The screw length used is usually between 25 mm and 30 mm. Occasionally, the anatomy might portend itself to longer screw lengths, but care must be taken to avoid violation of the anterior cortex by more than one to two screw threads due to the risk for injury to the internal carotid artery anteriorly.²⁸

C2 Pedicle Screw Fixation

The C2 pedicle screw can now be placed. The starting point used for the C2 pedicle screw is more proximal and medial than the C2 pars screw (Figs. 45.8A and B). As an anatomic

Figs. 45.9A and B: (A) The placement of two intralaminar screws is possible. However, as demonstrated by this anterior-posterior radiograph, (B) one screw must have a starting point slightly more cranial than the other in order to accommodate the other screw.

landmark, we define the medial border of the pedicle by following the superior border of the C2 lamina laterally. This (ventral lamina) becomes the medial wall of the pedicle and defines our medial trajectory for the pedicle screw. The starting point is 5 mm lateral to the intersection of the lamina and medial wall of the pedicle. We aim 20–25° medially and 20–25° cranially to achieve the optimal trajectory for the pedicle screw (see Figs. 45.8A and B). Generally, it is better to err medially than laterally at this level because medially, the space available for the cord allows for small medial breaches without clinical consequence. In addition, because the medial cortical wall of the pedicle is very thick, it is much less vulnerable to violation. A lateral and caudal breach, however, can result in vertebral artery injury. We notch the starting point with a burr and then switch to a cervical pedicle probe. If we encounter resistance, we use a drill with a drill stop that we sequentially lengthen, so as to prevent plunging, under hand power. We then use a ball-tipped probe to palpate for any breaches, tap and then palpate again prior to placing the screw.

C2 Intralaminar (Translaminar and Laminar) Screw Fixation

The C2 translaminar screw is an excellent alternative to C2 pedicle or pars screw fixation if the anatomy does not allow for the latter. Lehman et al. examined the pull-out strength of the C2 pedicle screw versus C2 pars screw versus the C2 intralaminar screw under salvage conditions.²⁹ The authors concluded that the pedicle screw provided the strongest

pull-out strength, while the C2 pars screw and intralaminar screw were similar, or slightly in favor of intralaminar fixation.²⁹ This screw is placed within the lamina at staggered starting points in order to allow for two screws to be placed (one in each direction) (Fig. 45.9A). One can also use one type of screw on one side and another on the contralateral side. If using bilateral laminar fixation, one must plan carefully to start the first screw as cranially as possible so that there is enough room for the second screw from the opposite side (Fig. 45.9B). In order to ensure that the screw does not violate the ventral cortex, as well as to improve fixation, one can aim for the tip of the screw to exit the dorsal cortex far laterally. Attaching a rod to a laminar screw may seem a bit difficult to someone who has never tried it. But in reality, it is quite simple, since a rod from a C1 lateral mass to a C2 screw is simply a straight line. If bilateral laminar screws are utilized, one has to limit the amount of laminar decortication for the arthrodesis, since it can weaken the screw purchase.

OCCIPITOCERVICAL FIXATION CONSIDERATIONS AND OPTIONS

There are multitudes of modern fixation options across the occipitocervical junction. One option is the occipitocervical plate/rod system, which is probably the most commonly used. Recently, occipital condyle screws were described. Lee et al. concluded that the safest method for placing the occipital condyle screw was to use a lateral starting point that was approximately 3 mm from the

midpoint aimed 40–45° medially.³⁰ This resulted in a 93% success rate for screw placement. A biomechanical study compared the use of the occipital condylar screw and traditional occipital plate/rod fixation and concluded that use of the occipital condylar screw along with a small eyelet into which a short screw was placed into the skull was similar in flexion/extension as well as lateral bending stability compared to plate/rod systems.³¹ Due to this biomechanical equivalency as well as the risk of injury to neurovascular structures when placing an occipital condylar screw (i.e. posterior condylar emissary vein, hypoglossal canal that contains the hypoglossal nerve and vertebral artery), we prefer to use plate and rod systems for occipital fusions.

When utilizing occipital fixation, it is important to ensure correct placement of the plate at the external occipital protuberance, where the bone is hardest and thickest, while avoiding skin problems. The external occipital protuberance is the second hardest bone in the body, following ones teeth. Therefore, a screw that is longer than 10–12 mm need not be bicortical to obtain great purchase. The greatest screw lengths will be those in the midline, while those more lateral will be significantly shorter. Typically screw length between 10 and 16 mm can be achieved at the midline. Tapping is essential prior to placement of occipital screws due to the extremely hard nature of the bone. Taking advantage of the anatomically favorable bone found in the midline is what modern-day occipital fixation techniques are based on. Just lateral to the midline, however, the occipital bone thins as you go more laterally and, therefore, does not provide fixation as robust as the midline. Biomechanically, this lateral bone demonstrates less pull-out strength and less insertional torque compared to their midline counterparts.³² Screw placement in the midline typically does not have to be bicortical, as the bone is mostly all cortical bone. The confluence of sinuses (the venous drainage for the cranium is the combination of the sagittal and transverse sinuses) can lead to brisk bleeding if punctured during inadvertent bicortical screw placement. In this case, calmly placing the screw in the prepared position will tamponade the bleeding and usually does not result in any clinical consequence.

When utilizing plate and rod fixation, it is our preference to utilize prebent or articulated rods instead of trying to contour our own rods. Due to the extremely high sagittal angle of the occipitoaxial angle, forming a bend that is adequate to accommodate the plate and the screws, can take multiple attempts. This can lead to notching of the

titanium rod and can predispose to rod breakage, inadequate stabilization and need for revision surgery. A titanium rod should only be bent in one direction. Unbending it in the opposite direction notches the titanium and makes it prone to early breakage. Given the long distance that this rod has to span from the plate to C1 or C2, it is already prone to breakage. Prebent rods are also typically reinforced to withstand fatigue breakage. Articulated rods are simple to use and obviate the need for complex bends.

Occasionally, the anatomy may not portend itself to C1 and occipital fixation points due to the extreme sagittal angle of the OC junction. For this reason, we prefer the posterior arch screw for C1 fixation because it usually lies more dorsal in the construct, making it easier to engage a rod that was to span C2 to the occiput. If this is still not feasible, we may skip fixation at C1 and obtain fixation at C2. It is still possible to obtain four fixation points in C2 with the aid of pars/pedicle screws and intralaminar screws.

Malalignment at the OC junction can be disabling because of setting the right length tension relationship of the esophagus and trachea as well as centering the head in the axial plane to ensure the visual fields stays centered and equal. An abnormally flexed position can make respiration and swallowing difficult. Conversely, if there is too much extension and rotation, balance and visual field problems can be disabling. We usually aim for an occipitoaxial angle between 0° and 30°.³³ More importantly, however, we use the preoperative radiographs to gauge our desired correction. If the patient is positioned at the same occipitoaxial angle as the preoperative standing radiographs, this will usually be the appropriate position for setting the OC junction.

INTRODUCTION

Cervical instrumentation began in the late 1890s. In the following century, cervical instrumentation experienced vast improvements with the development of rigid fixation including anterior cervical plates, cervical cages, pedicle screws, and lateral mass and transarticular screws. After adopting these techniques, older methods of fixation such as posterior wiring and hooks have gradually been abandoned.

POSTERIOR SPINOUS PROCESS AND FACET WIRING

In 1942, Rogers described a surgical technique for the treatment of fracture dislocations of the cervical spine in which posterior wiring and fusion were performed. This technique has subsequently been used in the last century for cervical fracture dislocations and instability. However, posterior wiring has fallen out of favor because it is limited by the presence of key portions of the posterior elements. Moreover, wiring is biomechanically not as rigid when compared to other types of instrumentation.¹

In the Rogers interspinous wiring technique, a single cable is looped through a hole at the base of the superior spinous process with the loop passing above its respective process. The free end of the cable is then passed through the inferior spinous process and the inferior loop encircles

the inferior spinous process. The cable is then tightened. In the Bohlman triple-wire technique, the first cable creates an interspinous loop in a similar manner as that of Rogers, then it is passed through separate holes in the superior and inferior spinous processes, respectively, and the ends of these cables are passed through holes in the two autologous bone grafts. The cables are then tightened. Branch et al. used methyl methacrylate, which encased the entire construct, and a standard interspinous wiring technique to treat the traumatic fracture dislocations of the lower cervical spine.² In general, posterior wiring techniques are simple to perform and use inexpensive materials. Although wiring is biomechanically inferior to screw fixation, it can effectively reconstitute the posterior tension band and can resist flexion forces in the cervical spine.

Each wiring technique carries certain risks with it. Spinous process wiring has the potential complication of penetration of the spinal canal and subsequent spinal cord injury. Care should be taken to place the starting points at the base of the spinous process. Intraoperative radiographs can be obtained before passing the wire to ensure correct placement. Facet wiring and Southwick's technique have a possible risk of nerve root and/or vertebral artery injury with the drilling and passage of the wire through the inferior facet. This risk is reduced with the placement of an instrument (Penfield #2) in the facet joint to prevent penetration of the superior process of the vertebra below.

CERVICAL LAMINAR HOOKS

Modern techniques of posterior cervical instrumentation in the subaxial cervical spine include the use of pedicle screws, lateral mass screws, and laminar hooks. These options are listed in the decreasing order of technical difficulty and biomechanical fixation strength. A comparative study found that laminar hooks performed well in resisting flexion and extension but were less effective in resisting lateral bending and axial rotation, allowing greater range of motion than screw constructs.³ Use of cervical laminar hooks has been limited by the potential for creating iatrogenic central stenosis. However, a study found that 95% of the hooks do not deform the dural sac in either the supine or prone position suggesting hooks are firmly seated and do not migrate.⁴

Indications for cervical hooks include patients with intact lamina who require posterior fixation. The

contraindications for cervical laminar hooks include trauma to the posterior cervical arch, bone tumor in the arch, spinal cord edema, or canal stenosis (when >3 segments need fixation). Studies have shown that hooks inserted in the cervical spine have a close anatomical relationship with the neuraxis, and should not be used at stenotic levels.⁴ Cervical hooks can be used individually (e.g. Halifax clamps or Apofix) or combined with pedicle or lateral mass screws.

The patient is placed in the routine prone position in Mayfield tongs. A standard midline incision is made and the lamina is exposed up to the laminofacet junction. Laminar hooks are specifically contoured to the anatomy of the cervical lamina. However, it may be necessary to sculpt the posterior lamina with a high-speed burr so that the hook fixes appropriately. Figures 46.1 to 46.6 outline the step-by-step technique for placing laminar hooks.

Fig. 46.1: Preparation.

Fig. 46.2: Implantation of the cephal ends.

Fig. 46.3: Implantation of the caudal ends.

Fig. 46.4: Fastening the clamps.

Fig. 46.5: Cutting off the prominent parts.

Fig. 46.6: The bone transplantation bed and the bone graft are prepared to be placed.

Fig. 46.7: The patient is placed in a prone position with the head fixed by a head fixator and the head held in a slightly flexed position.

There are a few clinical outcomes reported on the use of laminar hooks. Biomechanical studies³ demonstrated that laminar hooks appear to be a good alternative to pedicle screw fixation (PSF).

LATERAL MASS SCREWS

Lateral mass screw fixation was originally reported by Roy-Camille in the 1980s and further developed by Anderson, An, and Magerl.⁵⁻⁸ This technique has since become the mainstay of fixation in the posterior cervical spine.

Screw fixation in the lateral mass fixation can be used to treat cervical spondylosis with myelopathy,⁹ radiculopathy, traumatic injuries (including burst fracture, dislocation, tear drop fracture, unilateral facet fracture/dislocation, bilater-

al facet fracture/dislocation, lateral mass fracture, pedicle fracture, lamina fracture, etc.),¹⁰ cervical instability, neoplasm, decompression,¹¹ wide laminectomies for tumor resection or other pathologies, failure of previous fixation with other devices,¹ degenerative disorder of the cervical spine,^{10,12} congenital cervicothoracic stenosis, and deformity correction such as postsurgical kyphosis^{11,13} and cervical hyperlordosis.¹⁴

Contraindications to lateral mass fixation include comminuted, incompetent, or disconnected lateral masses resulting from trauma, excessive bony resection following a foraminotomy, or an aberrant vertebral artery.¹¹

Patients are positioned in the prone position with the head in a Mayfield clamp (Fig. 46.7). In order to aid in visualization, the shoulders are pulled down and taped to the sides of the bed. Excessive traction should be avoided as injury to the brachial plexus can occur. A standard midline posterior approach is performed exposing the lamina, facet joints, and lateral masses. It is critical to have good exposure of the lateral border of the lateral mass as well as each facet joint to be fused. A 2-mm round burr is then used to decorticate each facet joint. The center of each lateral mass is identified. It should be noted that the vertebral artery lies anterior to the center of the lateral mass. The starting point varies (Table 46.1) according to the surgeon's preference. It is the senior authors' preference to start center on the lateral mass (Roy-Camille technique). A 2-mm diameter pilot hole is then made with a burr taking care to be collinear with the other levels. The trajectory of the screw should be parallel to that of the facet joint. A Penfield #4 dissector can be placed in the facet joint to guide the cranial caudal trajectory of the screw. A drill

Table 46.1: Lateral mass screw techniques from different authors.^{1,2}

	Methods	Roy-Camille	Magerl (Figs. 46.8A to C)	Anderson	An
Entry point	Mediolateral	Midpoint	2 mm medial to midpoint	1 mm medial to midpoint	1 mm medial to midpoint
	Craniocaudal	Midpoint	2 mm cranial to midpoint	Midpoint	Midpoint
Trajectory angle	Mediolateral	0°–10° lateral	20°–25° lateral	10° lateral	30° lateral
	Craniocaudal	0°	Parallel to facet joint	30°–40° cephalad	15° cephalad

with a depth stop of 14 mm is used to drill the path of each screw in both upward and outward directions according to Magerl (Figs. 46.8A to C). Typically, the appropriate angulation involves the drill touching the spinous process of the inferior vertebrae being instrumented. Some surgeons prefer to place lateral mass screws in a bicortical manner. In this situation, a depth stop is not used as the surgeon has a tactile sensation when crossing the second cortex of the lateral mass. It should be noted that the exiting nerve is at risk when placing a bicortical screw (i.e. C5 nerve with a C5 lateral mass screw). A ball tip feeler can be used to confirm that each drilled hole has four walls prior to screw placement. Liquid Gelfoam or Floseal can also be pressurized into the tapped hole to ensure that it has a floor. Extravasation around the lateral mass or into the facet joint indicates that there may be a bony defect present. It is the senior author's preference to tap each hole prior to screw placement to avoid cracking the lateral mass during screw insertion. It is also our preference to drill and tap the lateral mass screws prior to a laminectomy to minimize passing instruments over the spinal cord during the procedure. Typical screw sizes in the lateral mass are 3.5 mm in diameter and 14 mm in length. Variable bias screw heads can be used to ease the placement of the final rod. Local autograft bone from the posterior elements mixed with allograft, if necessary, is then placed over the decorticated lateral masses and into the appropriate facet joints for the fusion following screw placement (Figs. 46.9A to O).^{9,15}

Patients are instructed to wear a rigid, semirigid, or soft collar for at least 6 weeks postoperatively. For patients with cerebral palsy, a halo-vest can be applied for at least 8 weeks followed by additional use of a semirigid collar for another 4 weeks.

Several studies report that lateral mass fixation is simple, safe, and effective^{1,15–17} compared to other fixation techniques.¹⁵ Lateral mass fixation can provide better immobilization than anterior plating¹⁷ and is associated with maintenance of alignment and a low complication

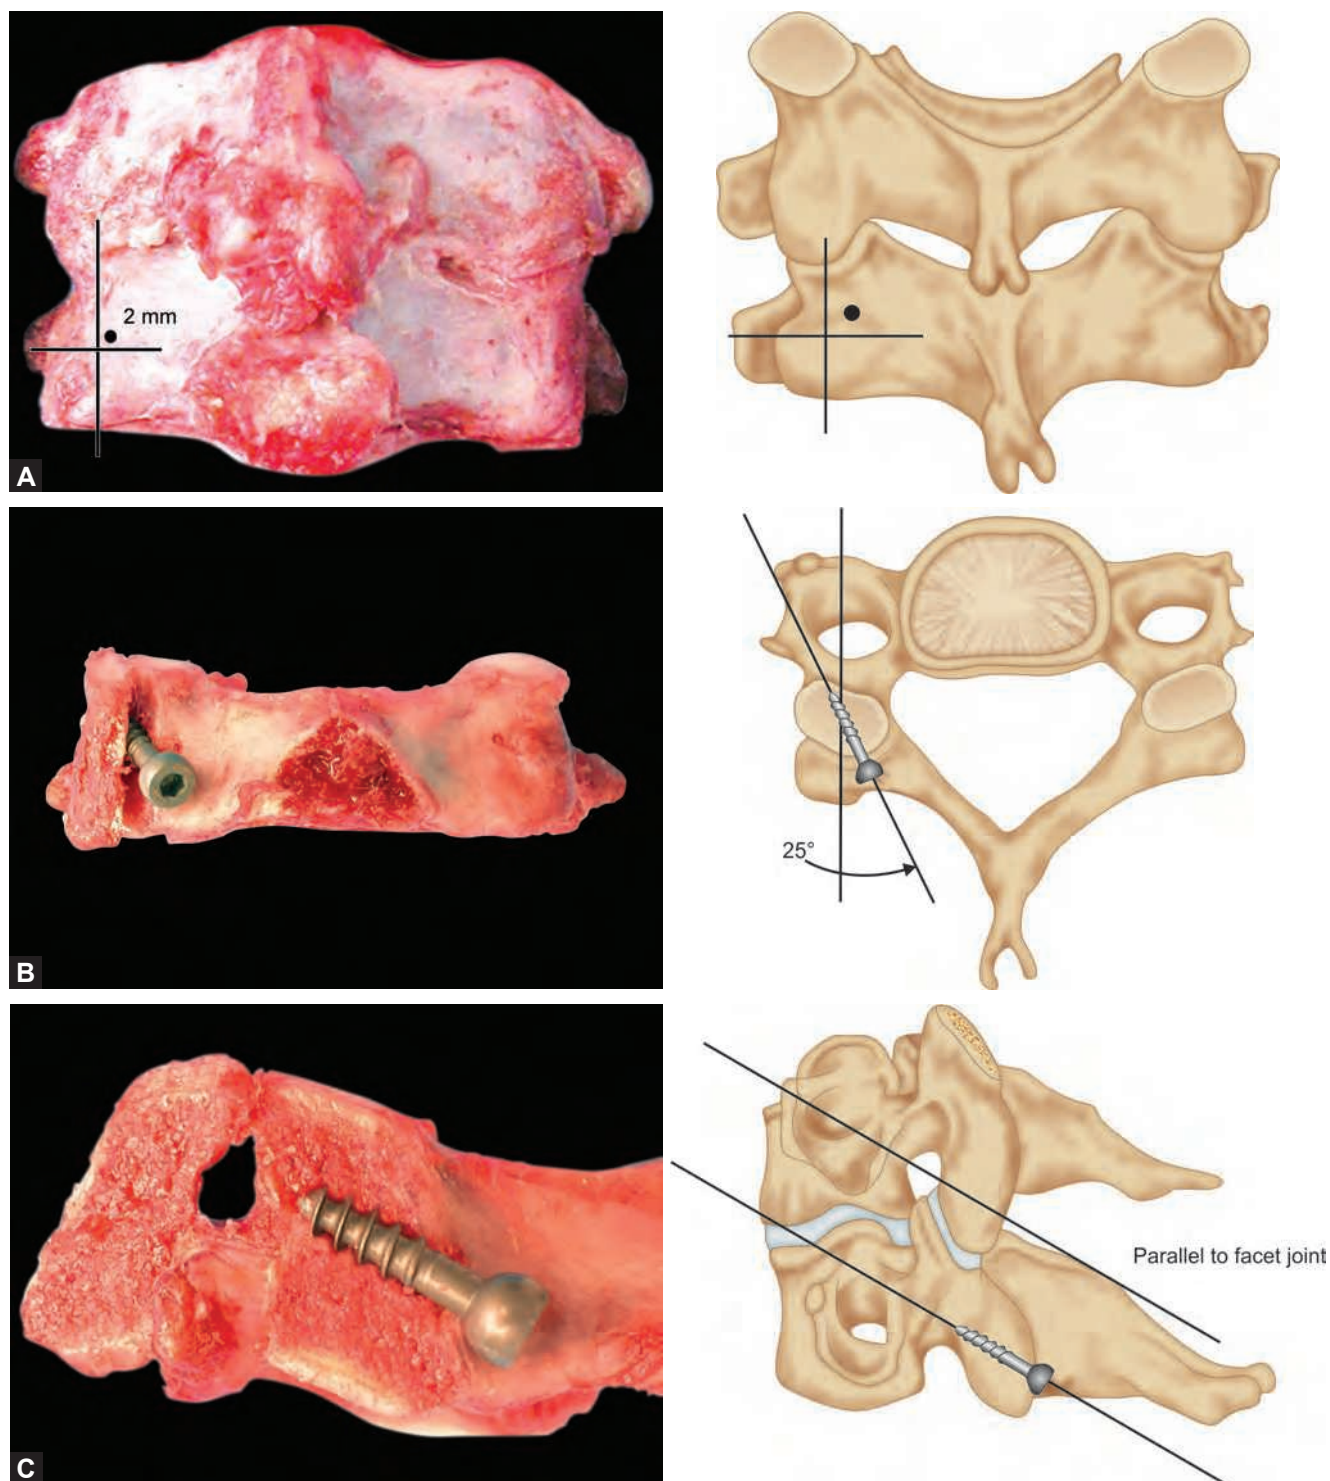

rate.^{1,10} At 14-month (4–35 months) clinical and radiologic follow-up, Wu et al. reported substantial bony fusion and good clinical results.¹ The authors caution against unilateral fixation as it creates a “hinge effect” and is less stable than bilateral fixation.¹⁸

Complications (6.2%) associated with lateral mass screw fixation include nerve root injury, spinal cord injury, facet violations, iatrogenic foraminal stenosis, vertebral artery injury, broken screw, lost reduction, pseudoarthrosis, screw avulsion, and screw loosening.^{9,19} Proper screw placement can reduce these complications. Facet violation is associated with lower trajectory angles in the sagittal plane, while violation of the vertebral artery (VA) foramen is related to lack of lateral angulation in the axial plane.¹⁵ It is necessary to preoperatively determine the location of the vertebral artery during lateral mass screw placement to minimize complications.²⁰

CERVICAL PEDICLE SCREW FIXATION

Cervical PSF was developed by Abumi et al. and has many major biomechanical advantages compared with lateral mass fixation.^{12,21–24} However, transpedicular stabilization has generally been considered a risky surgery due to the potential for serious injury to the surrounding structures, such as the spinal cord, nerve roots, and vertebral arteries.^{25,26} Authors have described different surgical techniques, including computer navigation system, to increase the accuracy of screw placement and to decrease clinical complications.

Cervical PSF has been reported to provide superior stability for reconstruction of the cervical spine.^{1,22,26–28} Unstable three-column injuries, fixation following cervical osteotomy, or postlaminectomy kyphosis are particularly suitable for cervical PSF because of its added biomechanical strengths. In patients with severe osteopenia, the strong initial fixation of pedicle screws can eliminate the necessity of postoperative halo-vest immobilization.^{29,30} Moreover, for the patients whose laminae or lateral masses are

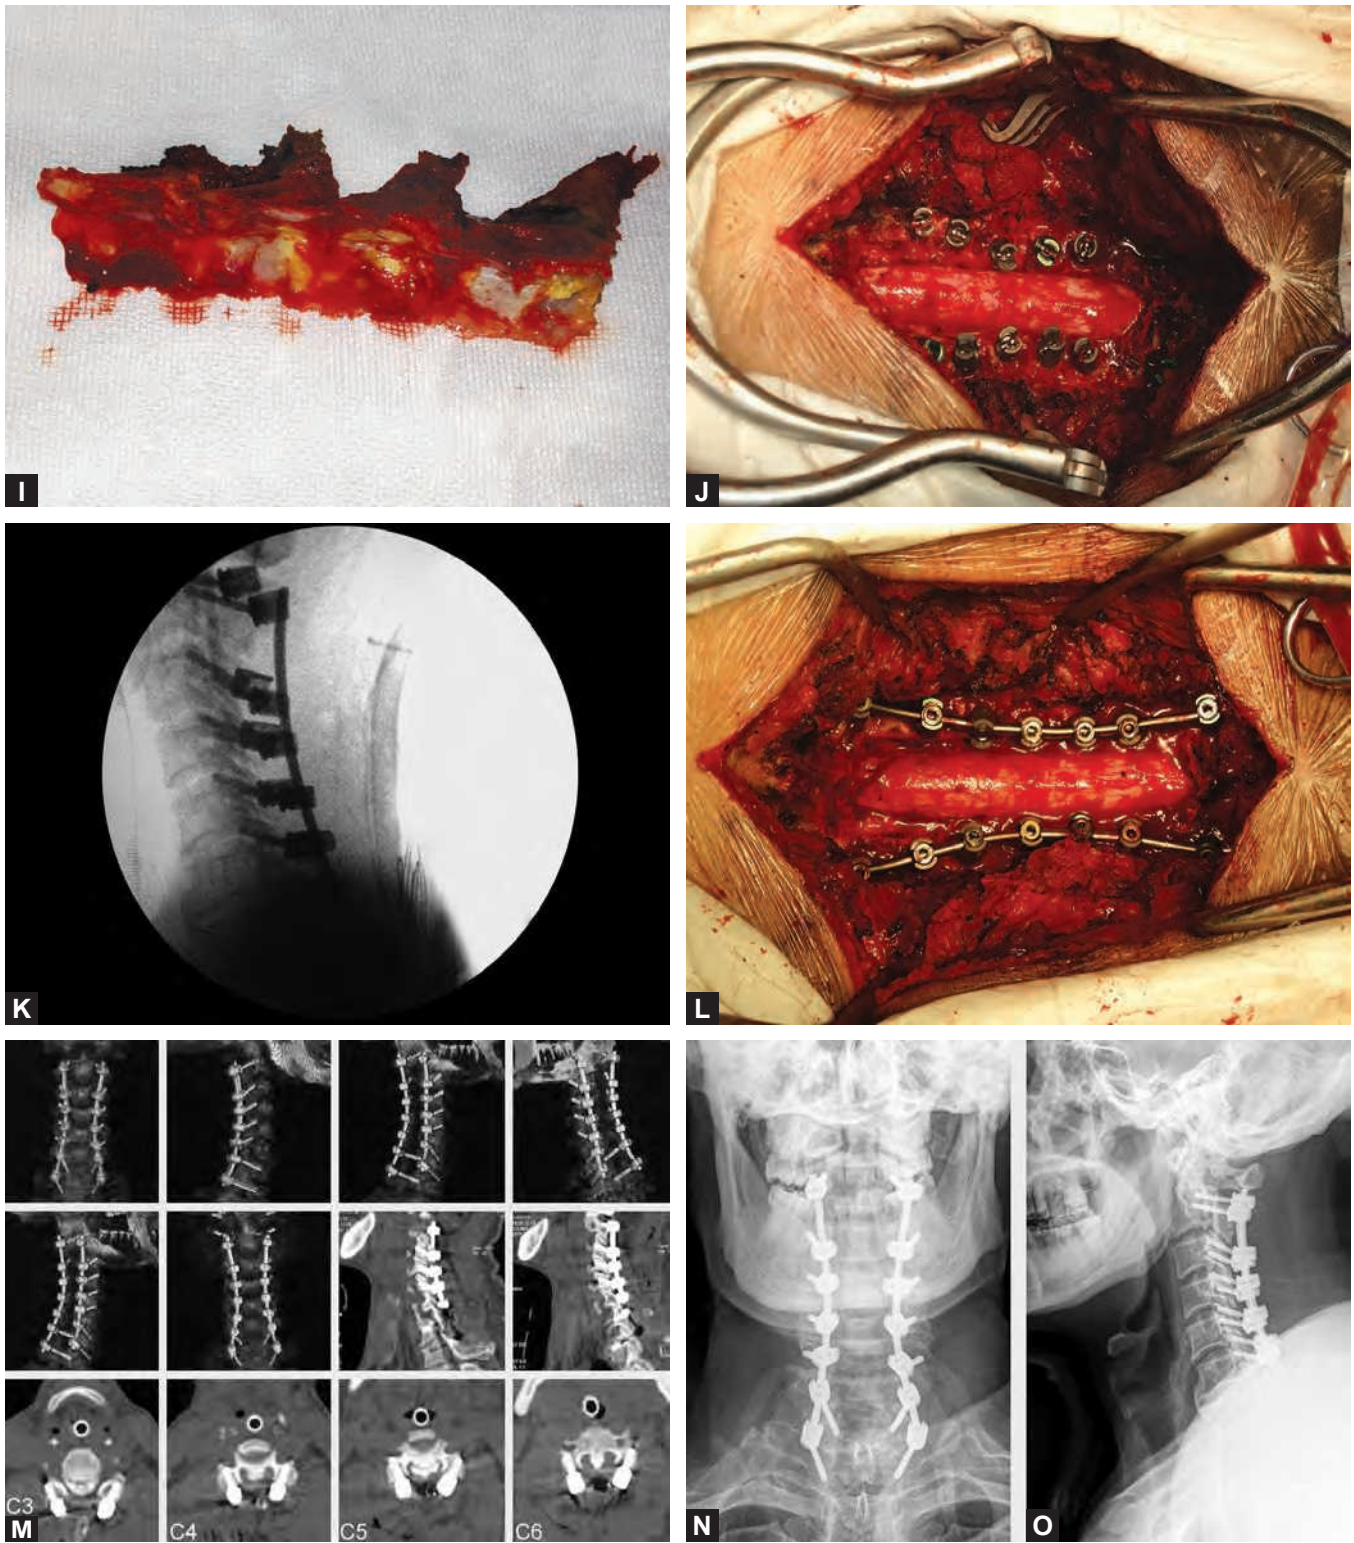

Figs. 46.8A to C: Lateral mass screws insertion using Magerl technique in cadaver specimen: (A) Entry point. (B) Horizontal screw trajectory. (C) Sagittal screw trajectory.

compromised, PSF can be particularly useful.^{28,31} Cervical PSF is a three-column fixation system with a high cor-

rection capability and low incidence of implant failure compared to conventional hook and wire constructs.³²⁻³⁵

Figs. 46.9A to H: A patient with the ossification of cervical posterior longitudinal ligament and spinal canal stenosis treated by lateral mass screws fixation with Magerl technique. (C3–C6: lateral mass screws; C2, C7, and T1: pedicle screws). (A to C) Preoperative X-ray, (D) CT, and (E) MRI showed the ossification of cervical posterior longitudinal ligament with spinal canal stenosis. (F) Exposed lateral masses and prepared the screw trajectory (right is cephalic and left is caudal). (G) After C2, C7, and T1 pedicle screws insertion, the C3–C6 lateral screw holes were drilled, tapped, and plugged up with the bone wax. (H) Laminectomy performed in C3–C7 level.

Figs. 46.9I to O: (I) Resected lamina after decompression. (J) Inserted lateral screws after decompression. (K) Fluoroscopy to confirm the screws position and whether rod contour was proper or not. (L) After fixation and local autogenous bone graft fusion. (M to O) Postoperative X-ray showed that all pedicle and lateral screws are in good positions, and cervical curvature was restored. (CT: Computed tomography; MRI: Magnetic resonance imaging).

Table 46.2: Subaxial cervical pedicle's width, height, and transverse angulation.

	Average pedicle width (mm)	Average pedicle height (mm)	Average pedicle transverse angulation (°)
C3	5.1 ± 1.1	6.2 ± 1.2	50 ± 2
C4	5.7 ± 0.9	6.4 ± 1.0	49 ± 3
C5	5.9 ± 1.2	6.3 ± 0.9	46 ± 5
C6	6.3 ± 1.1	6.5 ± 1.0	43 ± 3
C7	7.1 ± 1.0	6.5 ± 1.3	34 ± 4

Hasegawa et al. considered destructive lesions to be indications of cervical PSF. On the other hand, they noted that cervical spondylotic myelopathy and ossification of the posterior longitudinal ligament were not the indications secondary to the potential risk of vertebral artery or nerve injury.³⁶

In a systematic review, Abumi et al. concluded that infection at the posterior elements of the cervical spine, a pedicle destroyed by tumors or injuries, an absent or extremely small pedicle, a pedicle of the vertebra with major anomalies of the vertebral artery, and an extremely oblique angle of the pedicle axis from the sagittal plane are contraindications of cervical pedicle screw insertion.²⁸ The outer pedicle diameter of most cervical pedicles in previous morphometric studies is >5 mm making pedicles' screw insertion possible. Cervical pedicles that do not have a medullary canal secondary to sclerotic change or pedicles with extremely small diameters are not suited for screw insertion.²⁸

Sufficient preoperative imaging studies of the morphometric details of the cervical pedicles are critical (Table 46.2).²⁸ Onibokun et al.'s radiological and anatomical study suggests that preoperative computed tomography (CT) scans before cervical transpedicular fixation should be thoroughly analyzed for pedicle diameter, length, and direction, and tailored for each patient.³⁷ Even in the same vertebra, the diameter between the left and the right pedicle can be different depending on vertebral artery dominance. In addition, before cervical pedicle screw insertion, preoperative investigation of the course of the vertebral artery based on magnetic resonance imaging (MRI) or CT angiogram is mandatory to prevent serious complications.³⁸

A standard mindline posterior approach is used and the lateral masses are completely exposed. Identifying the starting point and trajectory in the horizontal plane is critical for correct screw placement.²⁵ Since Abumi et al.

Fig. 46.10: Cadaver specimen: the technique relying on anatomical landmarks for CPS (cervical pedicle screw) insertion similar to Jeanneret and Hacker's technique for C3–C6. The entrance point is 3 mm below the superior facet joint on a vertical line in the middle of the articular mass. The drill is angled 45° medially (average 40–45°), and parallel to the contralateral lamina in axial plane and parallel to the endplate in sagittal plane.

first described cervical pedicle screw (CPS) fixation, other techniques using CT navigation have been developed and adopted to increase the safety of cervical pedicle screw placement.

Karaikovic et al. found that the location of the pedicle was unique at each cervical level.³⁹ In an anatomical study, Jeanneret et al. found that the entrance point of the pedicle is 3 mm below the superior facet joint on a vertical line drawn in the middle of the lateral mass.⁴⁰ The drill is then angled ≈45° medially, depending on preoperative CT scan templating (average 40–45°).⁴⁰ Hacker et al. suggested using the angle of the contralateral lamina as an intraoperative guide to the correct angle of medialization.⁴¹ The drill is then advanced in a line parallel to the endplate (Fig. 46.10).⁴⁰ Since the entry point at each subaxial cervical level is unique and the tolerance for error is small, using landmarks to the cervical pedicle entrance is insufficient for accurate and safe placement of pedicle screws.^{39,42,43}

A safer technique for pedicle screw placement is exposing the medial, superior, and inferior walls the pedicle by performing a laminoforaminotomy (the funnel technique).^{23,44–49} Several surgeons have advocated direct pedicle exposure.^{43,45,47–49} The pedicle-perforation rate using this technique has been reported to be 6.7%^{43,50} by Abumi et al. Using this technique, Karaikovic et al. reported that cervical pedicle screws were placed correctly (83.2%); the majority of the perforations were at C3, C4, and C5.⁴⁹

Fluoroscopy can be used as well to aid in the placement of cervical pedicle screws. The pedicle can be seen along its axis as a cortical circle on the fluoroscope. Pilot holes can then be created with a cervical drill at the center of the cortical circle. Using fluoroscopy, Zheng et al. reported an overall accuracy of 83.3% with a critical breach only 3.3% of the time.^{49,51}

Computed tomography guidance and the use of navigation can also be useful when placing cervical pedicle screws.^{44,47,52-56} Several studies have shown that navigation provided a higher accuracy of screw placement with less radiation exposure compared to conventional methods particularly in a deformed or pediatric cervical spine.⁵⁷⁻⁶¹ There are several navigation systems available for cervical pedicle screw placement. Two-dimensional fluoroscopic navigation is inexpensive and easy to operate; however, it does not provide axial images making it unsuitable for the cervical spine.^{62,63} Intraoperative CT (iCT) navigation systems have many advantages and eliminate almost all of the drawbacks of other navigation systems.⁶⁴⁻⁷⁰ These systems are highly accurate, have short data acquisition times, and do not require surgeon-dependent registration or open spinal exposure.^{64-66,69,70} Radiation exposure and cost are the main limitations of an iCT navigation system.⁷¹ Hott et al inserted 96 screws in 30 patients and reported that only 2 screws perforated the cortex (Figs. 46.11A to L).

The vertebral artery typically enters the cervical spine through the C6 transverse foramen. As such, placement of a C7 pedicle screw is distinctly different from the placement of pedicle screws at C3–C6. In addition, the average pedicular width and height of C7 are also larger measuring 6 mm and 5.8 mm, respectively.⁷² Prior to placing C7 pedicle screws, preoperative axial CT and MRI studies need to be considered to ensure that the vertebral artery does not enter at C7. The CT scan can also be used to measure the dimensions and angulation of the C7 pedicle. The average pedicle angulation of C7 in the transverse plane is 33.3°.⁷² The starting point is typically just caudal to the C6/C7 facet joint and slightly lateral to the midline of the lateral mass (Figs. 46.12A and B).²⁸ The relationship of the starting point with the C6/C7 facet can be verified on the sagittal CT view of the C7 pedicle. Despite the relatively larger size of the C7 pedicle, Barrey et al. assess the feasibility of C7 pedicle screw placement using anatomical guidelines alone and found that morphological guidelines were not sufficient to ensure safe screw placement. The authors recommended performing a laminoforaminotomy with direct palpation of the pedicle.⁷²

Typically, after the screw path is drilled and tapped, a 3.5-mm diameter by 18–24-mm length screws are appropriate for C3–C7.²⁸ Following screw placement, meticulous decortication of the facets and lateral masses should be performed with a burr for bone fusion.²⁵

Intraoperative neurological monitoring using motor evoked potential (MEP), somatosensory evoked potential (SSEP), and free running electromyogram (EMGs) is critical for assisting in the accuracy and safe placement of cervical pedicle screws.^{73,74} Djurasovic et al. found that EMG stimulation thresholds of >15 mA reliably predicted acceptable screw position. Values below 10 mA were associated with screw malposition and required exploration and potential removal.⁷⁵

Numerous studies have reported on the ability for cervical pedicle screws to help in achieving high fusion rates with excellent correction of cervical deformity.^{31,50} Abumi et al. report that solid bony fusion was obtained in all patients except in those with metastatic tumor who did not receive bone grafting.³¹ Yukawa et al. reported that 100 consecutive patients with unstable cervical spine injuries underwent cervical PSF with only 2 cases of instrumentation failure and loss of correction. A solid posterior fusion was achieved in 95% of patients.²⁶

Despite numerous studies on the biomechanical benefits and superior correction of cervical deformity with cervical PSF, possible injury to the vertebral artery and nerve roots is of concern.²⁸ The complicated anatomy of the cervical spine and the variation of pedicle anatomy have been associated with a relatively lower accuracy and higher risk of severe neurovascular complications when compared to other regions of the spine.⁷⁶ A medially placed screw could injure the spinal cord while a laterally placed screw could injure the vertebral artery. An inferiorly or superiorly placed screw could injure the exiting nerve root.

Yukawa et al. reported a 3.9% pedicle perforation rate with 1 vertebral artery injury in 144 patients.²⁵ Abumi et al. reported a 6.7% pedicle perforation rate with 1 vertebral artery injury in 180 patients. However, other authors have reported up to a 30% malposition rate (including 9% critical breach rate)⁷⁷ and a 3.4% vertebral artery injury rate.^{36,77} As a result, some authors have advised that midcervical pedicle screws posed significant additional risk and should only be placed by very experienced spine surgeons in the setting of destructive lesions only.^{36,77} Less-experienced spine surgeons should perform cervical pedicle screw insertion with the assistance of experienced surgeons.⁴³

Figs. 46.11A to H

Figs. 46.11A to L: The patient with cervicothoracic metastatic carcinoma was treated with decompression and pedicle screw fixation (C5–T4). (A) A reference array was attached to the spinous process. (B) The iCT scan was then obtained and transferred to the image-guidance workstation. (C) After automatic registration, the surgeon checked the accuracy of navigation by the bony landmark. If the accuracy of navigation was unacceptable or doubted during the operation, additional CT scan and registration were necessary until the accuracy of navigation was acceptable. (D) The surgeon drilled, tapped, and placed the instrumentation under the iCT navigation guidance of three-dimensional, coronal, axial, sagittal, and probe's eye view. After all pedicle screws were placed, the accuracy of placement of all pedicle screws was first assessed by an iCT control scan. Different 3D CT images show that the all the pedicle screws were implanted exactly in the pedicles. (E) Lateral CT image with a reference array attached to the adjacent spinous process. (F) A-P (anterior posterior) CT image. (G) Oblique CT image (right). (H) Oblique CT image (left). (I) Axial CT image (C5). (J) Axial CT image (C6). (K) Axial CT image (C7). (L) Postfixation image. (iCT: Intraoperative computed tomography).

CERVICAL TRANSARTICULAR SCREW FIXATION

Roy-Camille and Saillant pioneered the use of transarticular screw fixation in the subaxial cervical spine in 1972.⁷⁸ Although it has not been widely adopted, facet screw fixation has been used by a select few surgeons over the last several decades.⁷⁹ Takayasu et al. and Xu et al. have reported the safe placement of cervical transarticular screws (Figs. 46.13 and 46.14).⁸⁰

Transarticular facet fixation is applicable to trauma, posterior fixation following laminectomy, posterior fixation following anterior cervical surgery,⁷⁸ and as a salvage technique for failed lateral mass fixation.¹¹ Transarticular screw fixation can also be used in conjunction with other posterior fixation techniques including posterior wiring techniques.¹¹ It should be noted that in biomechanical studies, stand-alone transfacet screw fixation was found to be inferior when compared to lateral mass screw

Figs. 46.12A and B: The entrance point is just caudal. The entrance point is just caudal of the C6/C7 facet joint and slightly proximal to the notch in the craniocaudal direction. The drill is angled 35° medially (average 30-40°) and parallel to the endplate in sagittal plane.

Fig. 46.13: Views of transarticular facet screws in the cervical spine. Source: DalCanto RA, Lieberman I, Inceoglu S, et al. Biomechanical comparison of transarticular facet screws to lateral mass plates in two-level instrumentations of the cervical spine. *Spine (Phila Pa 1976)*. 2005;30(8):897-2.

Fig. 46.14: The "safe quadrant" of the articular pillar. There are no artery or nerve root courses.

fixation.⁸¹ However, transarticular screws have greater pullout strength secondary to multicortical fixation.⁸²

Transarticular screw fixation can be used in all but the most in a caudal segment of a fusion. DalCanto et al. described the starting point as 2-mm caudal to the mid-point of the lateral mass with a 40° caudal and a 20° lateral angulation. The screw should traverse as perpendicular as possible to the articular surface. Jost et al. reported the mean optimal medial-lateral insertion angles [\pm standard deviation (SD)], mean sagittal insertion angles, and

the mean trajectory lengths (Table 46.3).⁷⁸ Navigation and/or fluoroscopy can be used to guide transarticular screw placement.⁸³⁻⁸⁵

Clinical studies have shown that after an average of 6 months, there were no signs of hardware failure.⁸⁶ Long-term follow-up (3 months to 5 years) continued to show no hardware failure with good fusion rates.⁸⁰

Complications associated with transarticular screw placement in the subaxial cervical spine include injury to the spinal cord, vertebral artery, or nerve root.

Table 46.3: The mean optimal mediolateral insertion angles (\pm standard deviation), the mean sagittal insertion angles, and the mean trajectory lengths.

	Mean optimal mediolateral insertion angles (°)	Mean sagittal insertion angles (°)	Mean trajectory lengths (mm)
C2–C3	23 \pm 5	77 \pm 10	15 \pm 2
C3–C4	24 \pm 4	77 \pm 10	14 \pm 1
C4–C5	25 \pm 5	80 \pm 11	15 \pm 1
C5–C6	25 \pm 4	81 \pm 8	16 \pm 2
C6–C7	33 \pm 6	100 \pm 11	23 \pm 4

In addition, if a screw is placed too close to the caudal edge of the inferior facet, a small portion of the inferior facet below the screw could fracture.⁸⁷

KEY POINTS

- Knowledge of cervical anatomy is critical to instrumenting the subaxial cervical spine. Preoperative planning of screw sizes and trajectories as well as vertebral anatomy using CT or MRI should be performed before every case.
- Understanding contraindications to certain types of fixation methods is important. Fractures of the lateral mass or pedicle should be identified preoperatively for surgical planning.
- Placement of cervical pedicle screws is possible when performed by experienced surgeons. The complications of cervical pedicle screw placement (C3–C6) can be catastrophic and the benefit must be weighed against the risks of the procedure. We advocate that if the vertebral artery is not within the C7 transverse foramen, then pedicular screw fixation of C7 is generally safe.
- Use of navigation can be useful in the cervical spine and can avoid hardware malplacement, particularly in the cervical pedicles.

INTRODUCTION

Congenital lesions of the craniovertebral junction (CVJ) had long gone unrecognized. It was only after Chamberlain's seminal radiographic investigations in 1939 that basilar invagination and the other bony abnormalities of the CVJ were considered for antemortem diagnosis and treatment.¹ These lesions were initially managed by a posterior osteodural craniocervical decompression with dismal overall clinical results.²⁻⁴ In fact, when an irreducible, cranially translated, or posteriorly dislocated odontoid peg compresses the cervicomedullary junction ventrally, posterior decompression alone cannot be relied on to improve the prognosis of patients. In such a particular anatomical scenario, the posterior approach can provide only partial decompression, usually leading to an increase in ventral cervicomedullary junction compression.⁵

The transoral approach (TOA) originally described by Kanavel in 1917⁶ and subsequently refined through the contributions of many different pioneers^{4,7-11} can be regarded today as the standard approach for the treatment of irreducible anterior abnormalities that compress the cervicomedullary junction. Over time, the value of a straight anterior approach to extradural lesions of CVJ has been widely accepted, and variations of the TOA including the maxillary dropdown procedures have been described in patients with severe basilar invaginations or in cases of limited jaw mobility.^{5,8,12}

In this chapter, we describe the pearl and pitfalls of a standard TOA for CVJ malformations and the circumstances in which the TOA requires additional posterior craniocervical decompression.

TREATMENT PARADIGM

The factors dictating the surgical strategy in patients with CVJ malformations should be carefully evaluated preoperatively.^{4,11} First, the reducibility of the malformation should be investigated with spinal radiography and computed tomography (CT) scan, including dynamic flexion and extension views. Second, the site of encroachment (anterior or posterior) should be established. The indication for a TOA is irreducible ventral compression at the cervicomedullary junction (Figs. 47.1A and B). In the rare instances of fixed posterior compression, a standard foramen magnum decompression (FMD) is mandated. The primary treatment of a reducible CVJ malformation is posterior fixation and fusion. The extent of mandibular excursion and the severity of basilar invagination dictate the adjuncts to the TOA (i.e. the transmaxillary approaches).⁵ In our experience, a LeFort I Osteotomy is required in patients with platybasia and severe basilar invagination (odontoid tip projecting ≥ 20 mm above the Chamberlain's line).⁵ In addition, we favor the use of the open-door maxillotomy approach in patients with limited jaw mobility (i.e. an interdental space ≤ 30 mm).⁵

Figs. 47.1A and B: (A) Preoperative and (B) postoperative sagittally reformatted computed tomography scans, revealing basilar invagination, atlas assimilation, and atlantoaxial dislocation. The patient underwent single-stage transoral decompression and posterior occipitocervical fixation. The postoperative computed tomography scan shows removal of the odontoid with sparing of the anterior ring of the atlas. Onlay local autologous bone and iliac crest autograft was laid on the decorticated suboccipital surface and cervical vertebrae to promote solid fusion.

Congenital abnormalities of the CVJ occur in 30–50% of patients with Chiari I malformations.^{13–15} The surgical treatment of tonsillar herniation in the presence of irreducible ventral compression is still controversial. Recent literature suggests that a standard FMD in patients with fixed ventral encroachment and tonsillar prolapse is consistently associated with early, or more often, delayed neurological worsening (Figs. 47.2A and B).^{5,16} Symptomatic progression after FMD is due to further tonsillar prolapse (i.e. tonsillar ptosis) or an increase in ventral compression. According to our surgical experience, corroborated by recent literature,¹⁶ we suggest that an anterior decompression is effective in relieving obstruction of the subarachnoid space at the foramen magnum level in most patients with Chiari malformation associated with fixed CVJ malformation (Figs. 47.3A to C). This surgical treatment philosophy is based on the understanding of the critical role played by ventral compression at the CVJ level in the overcrowding of the posterior cranial fossa. After a generous anterior decompression, the ascent of the cerebellar tonsils into the posterior fossa with acquisition of a more rounded shape can generally be observed in most of patients. After the TOA for malformations of the CVJ, the risk of creating acute or delayed spinal instability is invariably high. In order to mobilize the patients as soon as possible, we have moved from performing a planned posterior fixation as a second procedure, to single-anesthesia transoral decompression and subsequent posterior occipitocervical fixation.

Figs. 47.2A and B: (A) Preoperative and (B) postoperative mid-sagittal T2-weighted magnetic resonance imaging of a patient with basilar invagination, fixed atlantoaxial dislocation, posterior atlas assimilation, severe brain stem compression, and hindbrain herniation. The patient underwent posterior fossa decompression (PFD) before referral to our unit. He experienced delayed deterioration in motor function 16 months after PFD. The postoperative MR scan disclosed a wide suboccipital craniectomy, increase in ventral brain stem compression, and the appearance of high-signal intensity at the cervicomedullary level. This case demonstrates that patients with irreducible or partially reducible craniovertebral junction malformations can develop delayed spinal instability after PFD with resultant increase in ventral cervicomedullary junction compression.

TRANSORAL APPROACH

Preoperative Assessment and Anesthesiological Considerations

The TOA can be performed when an interdental working distance of at least 30 mm is available. In cases of limited temporomandibular jaw mobility, a transmaxillary procedure should be considered. Instead of preoperative nasal and oropharyngeal culture, we favor the use of intravenous prophylactic ceftriaxone, which is continued for 24 hours postoperatively. A complete dental assessment is mandatory since transoral surgery is contraindicated in case of an active nasopharyngeal infection. A mandatory tracheostomy, routinely used early in our experience, has been replaced by fiberoptic nasotracheal intubation. We reserve prophylactic tracheostomies for the extended maxillo-tomy approach and in patients with brain stem compromise requiring prolonged ventilation.

Operative Positioning

The patient is positioned supine, with the skull rigidly placed in a three-pin fixation system. The head is extended from 10° to 15° according to the severity of basilar

Figs. 47.3A to C: (A) Preoperative midsagittal T2-weighted magnetic resonance imaging (MRI) scan of a symptomatic 64-year-old woman, revealing basilar invagination, atlas assimilation, hindbrain herniation, and cervical syringomyelia. (B) Early postoperative sagittally reformatted computed tomography scan after transoral decompression and occipitocervical fixation. No craniocervical decompression was performed. (C) Postoperative midsagittal T2-weighted MRI scan obtained at 3 months demonstrates relief of the cervicomedullary compression, ascent of the cerebellar tonsils, and shrinkage of the syrinx. This case clarifies that transoral approach achieves effective decompression of the cervicomedullary junction and, in turn, disimpacts the cerebellar tonsils with resultant syringomyelia resolution.

invagination. Positioning the patient in this manner helps the surgeon improve visualization of the pathology. The surgeon is seated at the top of the patient's head, and the surgery is fully performed with the aid of a binocular surgical microscope.

Instrumentation

A dedicated transoral system (Crockard transoral instruments, Codman Raynham, MA) including an oral/tongue depressor, attachable retractors, and extra-long instruments is the prerequisite for a safe and effective surgery. The retraction of the soft palate can be effectively obtained with two rubber catheters inserted through the nostrils and stitched laterally to the uvula (Figs. 47.4A and B).^{17,18} This maneuver greatly improves the exposure of the oropharynx and avoids the soft-palate splitting. Neuronavigation techniques or simple intraoperative fluoroscopy is used to provide confirmation of anatomic landmarks during the transoral procedure.

Operative Procedure

The procedure begins with infiltration of the posterior pharynx, with 1% lidocaine with epinephrine to facilitate dissection. Lateral fluoroscopy is used to confirm the position of the anterior tubercle of the atlas, which can be

Figs. 47.4A and B: Retraction of the soft palate. (A) Two rubber catheters inserted through the nostrils are stitched laterally to the uvula. (B) Traction of the catheters allows retraction of the soft palate, improving the exposure of the oropharynx.

easily palpated transorally, as well as to assess the cranio-caudal exposure obtained after positioning of the retractor system (Fig. 47.5). The identification of the anterior tubercle aids to maintain a midline trajectory. A linear midline incision of 2 cm in length along the median raphe of the posterior pharyngeal wall is carried through the mucosa and pharyngeal muscles (Fig. 47.6A). Monopolar cauterization is used to dissect the longus colli muscles and the anterior longitudinal ligament and to extend the dissection laterally from the anterior surfaces of C1 arch, the C2 vertebral body, and the lower clivus (Figs. 47.6B and C). The single-layer tissue flap is maintained laterally with

Fig. 47.5: Intraoperative lateral fluoroscopy of cervical spine demonstrating the identification of anterior tubercle of C1, which is the main landmark during the transoral approach to craniovertebral junction malformations.

tooth-bladed pharyngeal retractors. Bony resection is performed with small diamond and cutting burrs (Fig. 47.6D). Early in our experience, we aggressively removed the anterior arch of C1 to expose and progressively resect the odontoid peg in a piecemeal fashion. We now attempt to preserve the integrity of the anterior arch of C1 as much as possible, drilling the base of the dens and working inferiorly to the C1 arch. This bottom-up C1-sparing drilling technique generally requires removal of the inferior rim of the anterior arch of C1 to provide the effective angle of resection to the invaginated odontoid.¹⁹ When the base of the dens is transected, the odontoid is grasped with an odontoid rongeur and pulled inferiorly. This maneuver allows the surgeon the ability to sharply dissect and cut the alar and apical ligaments without pressure on the cervicomedullary junction and to remove, in an en bloc fashion, the invaginated odontoid (Figs. 47.6E and F). In fact, only after sectioning of the crucial ligament, can a proper dural protrusion into the operative field be appreciated (Fig. 47.6G). In patients with severe basilar invagination, this technique cannot be safely performed. In these patients the removal of the anterior arch of C1 is required to expose and remove the offending odontoid peg using the piecemeal technique. Transoral decompression ends when the pulsating dura mater protrudes into the surgical decompression site. After decompression, hemostasis is achieved and a piece of antibiotic wax is placed on the operative field against the dura; the mucosa and pharyngeal muscles are closed in a single layer with interrupted absorbable sutures (Fig. 47.6H).

Postoperative Management

Postoperatively, patients are transferred to the intensive care unit, where the endotracheal tube is maintained for 12–18 hours, depending on soft-tissue swelling and respiratory function. For the first 3 days after surgery, the patient should maintain an NPO (nothing by mouth) status, and nutrition should be administered intravenously. We do not favor the use of a nasogastric tube for enteral feedings. Periodic administration of hydrocortisone ointment to the lips helps to minimize postoperative swelling. Broad-spectrum antibiotics are administered for the first 72 hours. Patients are mobilized within 48 hours, and prophylaxis of postoperative deep vein thromboembolism with low-molecular-weight heparin is administered until they are fully ambulatory. A plain X-ray and a CT scan are obtained before discharge to evaluate the correct position of occipitocervical fixation and adequate CVJ decompression. The patients are placed in a rigid collar (Philadelphia collar) for 3 months.

Potential Complications

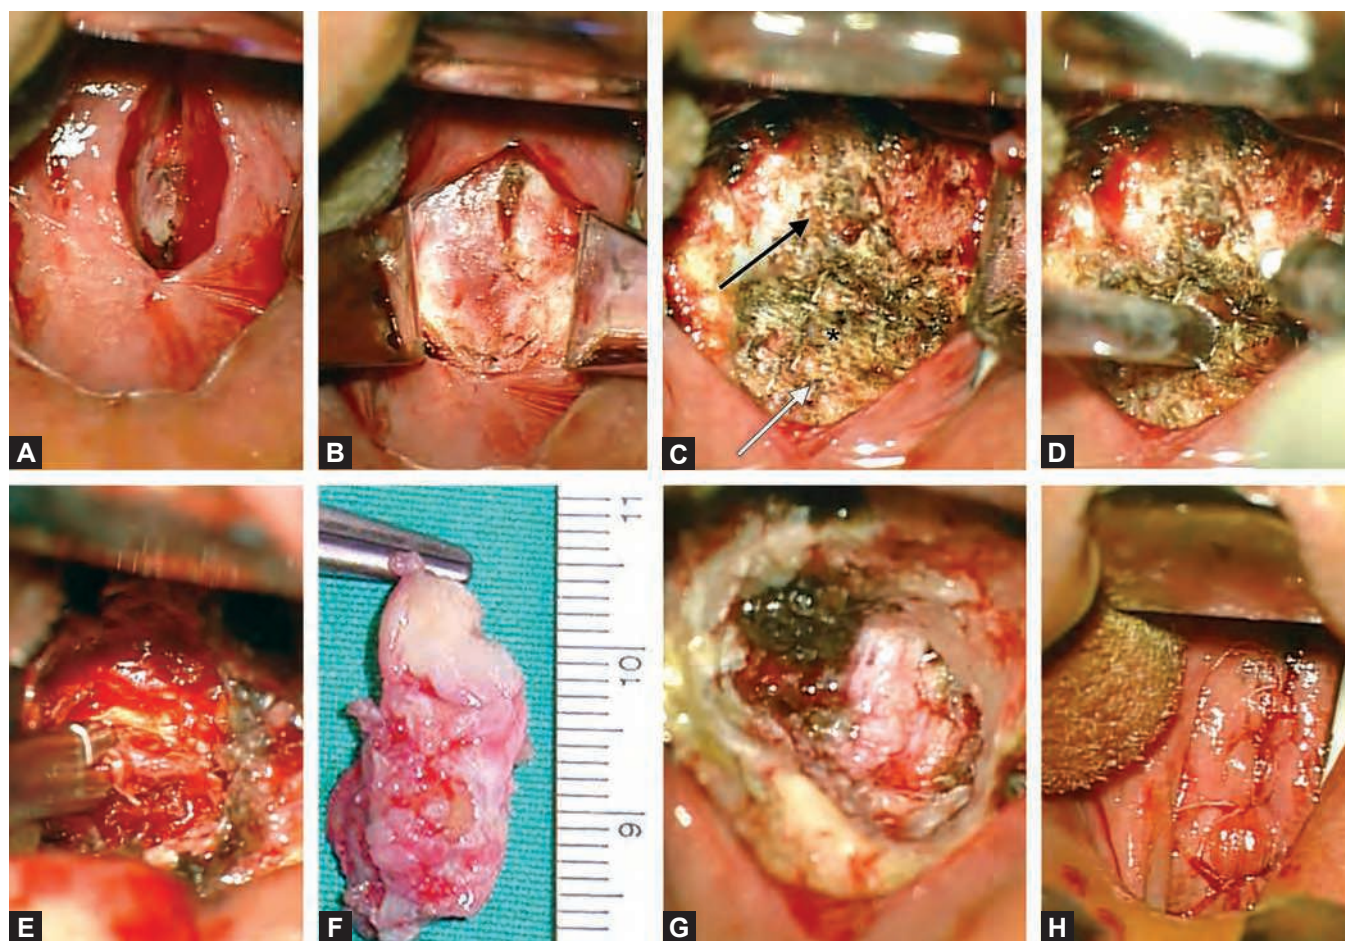

Several postoperative complications have been described after the TOA to CVJ.^{4,5,20–22} However, after an adequate learning curve and adopting some technical nuances, the occurrence of complications can be substantially reduced.

CSF Leakage and Meningitis

Cerebrospinal fluid (CSF) leakage due to inadvertent dural transgression can occur in the final stages of odontoid resection, especially in cases of severe basilar invagination.^{4,5,21} A CSF leak can lead to postoperative meningitis and should be treated aggressively when encountered. When the dura is clearly lacerated intraoperatively, primary dural repair should be attempted. The use of adipose tissue, fascia, and fibrin glue can be employed to enhance dural closure. In addition, placement of a lumbar subarachnoid drain is required at the end of the procedure.

Wound Dehiscence and Sepsis

Infection was initially considered a serious drawback to this operation because this approach is through a contaminated field. However, when the transoral procedure is used for extradural lesions of CVJ, the risk of postoperative infection is substantially lower. It has been suggested that the local resistance of the oral tissue to its own bacterial flora facilitates wound healing. Given the risk of

Figs. 47.6A to H: Intraoperative photographs of the patient presented in Figure 47.1. The tongue is oriented at the top of the photographs while the clivus is at the bottom. (A) A midline incision is made through the posterior pharyngeal wall in the median raphe. (B) The longus colli muscles are exposed and dissected with monopolar cauterization. (C) The anterior surfaces of the C1 arch (asterisk), the C2 vertebral body (black arrow), and the lower clivus (white arrow) are clearly identified. (D) The base of the dens and the inferior rim of the anterior arch of C1 are removed with a high-speed drill. (E and F) Transecting the base of the dens, the odontoid can be grasped with an odontoid rongeur, pulled inferoanteriorly and removed en bloc. (G) The decompression ends when the pulsating dura mater protrudes into the surgical field. (H) The mucosa and pharyngeal muscles are closed in a single layer.

wound dehiscence, the oral cavity should be periodically checked during the first week after the operation. A strict midline approach, judicious use of monopolar cautery, and a meticulous pharyngeal closure all reduce the occurrence of wound dehiscence. In the case of wound dehiscence, which generally occurs at the ends of the suture, the pharyngeal wound should be revised under general anesthesia.^{5,21}

Rhinolalia and Nasal Regurgitation

Incision of the soft palate with resultant fibrosis can lead to significant oropharyngeal morbidity, which ranges from velopharyngeal insufficiency to wound dehiscence

of the soft palate.²¹ In addition, an increased pharyngeal dead space as result of extensive bone removal at the CVJ promotes the poor apposition of the soft palate and nasopharynx, exacerbating velopharyngeal dysfunction. The occurrence of rhinolalia aperta and nasal regurgitation is significant functional deficit due to defects in the structure of the oropharynx and can be reduced by retracting, instead of cutting, the soft palate.

POSTOPERATIVE INSTABILITY

The TOA involves a significant osteoligamentous resection at the CVJ and predisposes to instability of this region. The risk of creating CVJ instability with TOAs to malformations

of CVJ has not been fully elucidated. Dickman et al.²³ in a retrospective analysis found that 40% of patients with fixed congenital osseous malformations exhibited C1–C2 instability after transoral surgery and required posterior fusion. Interestingly, patients who required posterior decompression of a Chiari malformation were at risk for developing instability as well. In fact, no consistent diagnostic criterion is available to predict whether and/or when a transoral odontoidectomy will cause instability in patients with CVJ malformations. Nonetheless, due to the potential morbidity of postoperative instability of CVJ, most authors advocate posterior fusion after transoral decompression.^{5,20,21,24,25} Instability after transoral surgery can occur in acute or delayed setting.^{20,23,26,27} In our early experience with 25 CVJ malformations treated with TOA, we have reported one postoperative death from acute dislocation of the axis on the day before a planned posterior fixation.²⁰

In order to eliminate the risk of acute postoperative instability and to mobilize the patient as soon as possible, we have moved from performing a planned delayed posterior fixation as a secondary procedure, to a one-stage transoral decompression and posterior occipitocervical fixation. Based on biomechanical studies, the integrity of the C1-ring is critical to minimize the risk of delayed instability of CVJ.²⁶ When the C1-ring is transected, a horizontal separation of lateral masses can occur, causing cranial settling of the C2 vertebral body, with resultant compression of cervicomedullary segment and neurological deterioration.²⁷ It is our policy, when feasible, to use the bottom-up C1-sparing drilling technique, in order to prevent the postoperative spreading of the C1-ring.

Several posterior systems of malleable rods with segmental wire fixation have been described in the literature, including Luque rectangle fixed at the upper cervical and occipital regions with steel wires, Hartshill-Ransford loop, threaded Steinmann pin, and Cotrel-Dubusset set. Wiring of the occiput may result in loss of vertical height due to telescoping of the implant. In addition, sublaminar wire passage can be dangerous for the spinal canal content. Occipital hook fixation has also been described, but has not widely adopted by spinal surgeons. Biomechanical studies have found that screw fixation of the occiput to the cervical spine provides the highest level of construct stiffness and is capable of resisting cranial settling and the geometrical loads applied at the CVJ.^{28,29} According to these findings, we favor the use of precontoured plate rod systems with bicortical screws in the occipital bone, C2 pedicles (when feasible), and lateral masses of the subaxial cervical spine.

Figs. 47.7A and B: (A) Midsagittal T2-weighted magnetic resonance imaging of the cervical spine, disclosing severe fixed posterior compression of the cervicomedullary junction. This 33-year-old woman complained of paresthesias in the limbs with attempted head extension. (B) Axial computed tomography slide confirms the posterior encroachment of the neuraxis by the abnormal lip of the foramen magnum.

Only local autologous bone and/or strips of iliac crest autograft are placed from the occiput to the posterior arch of C1 and to the laminae and lateral masses of the upper subaxial cervical vertebrae to promote solid fusion.

■ FORAMEN MAGNUM DECOMPRESSION

Isolated FMD is rarely indicated in patients with CVJ malformations. The main indication of this posterior approach is the occurrence of fixed posterior compression, which is an unusual finding (Figs. 47.7A and B).¹¹ In addition, isolated FMD should be considered in patients with basilar invagination due to horizontal angulation and shortening of the clivus associated with tonsillar prolapse, without significant ventral brainstem compression (Fig. 47.8).⁵ Finally, in patients with tonsillar prolapse and severe ventral compression in which the transoral decompression is not enough to ameliorate the overcrowding of the posterior cranial fossa, FMD should be performed in the same stage of occipitocervical fixation (Figs. 47.9A to F).⁵ In these patients, we perform an extra-arachnoidal osteodural craniocervical decompression directed toward decompressing cerebellar tonsils at the craniocervical junction and restoring CSF dynamics to normal.^{30,31}

Incision and Soft-Tissue Dissection

The patient's head is placed within the Mayfield head holder in a neutral position. A midline linear skin incision is

Fig. 47.8: Midsagittal T1-weighted magnetic resonance imaging scan disclosing tonsillar prolapse associated with shortening of the clivus, platybasia, and slight basilar invagination without significant ventral compression of the cervicomedullary junction. In this context, isolated posterior foramen magnum decompression should be considered.

(E) Postoperative sagittally reformatted computed tomography scan demonstrating removal of the odontoid with sparing of the anterior ring of the atlas. (F) Postoperative midsagittal T1-weighted MRI scan obtained at 6 months, showing ascent of the cerebellar tonsils and shrinkage of the syrinx.

planned from just the inion to the second or third cervical spine, depending on the extent of cerebellar herniation. A subperiosteal dissection of the squamous part of the occipital bone and the posterior arch of C1 is performed. The subperiosteal dissection of the spinous process and lamina of C2 is done only when a C2 laminectomy is planned. After the subperiosteal dissection, the convex external surface of the squamous part of the occipital bone with its bony prominences (i.e. inion, superior and inferior nuchal lines, external occipital crest) and the posterior aspects of C1 and C2 (when necessary) are exposed.

Bone Removal

The suboccipital region below the inferior nuchal line is carefully decompressed by removal of the posterior lip of the foramen magnum, typically very thick, using the high-speed drill with a cutting burr and a Kerrison rongeur. Once the suboccipital bone decompression is completed, a small craniectomy approximately 2.5 cm in width and 2 cm upward from the edge of the foramen magnum can be observed. At this point, the posterior arch of C1 and, when necessary, the lamina and the spinous process of C2 are removed.

Dural Decompression

The dural surface of the craniocervical junction is carefully examined under the operative microscope, and a band of thickened tissue on the outer surface of the dura can be observed at the craniospinal level. This fibrous band is removed and the dura is then opened in a linear fashion using a No. 11 blade. After a small opening in the dura is made, we favor the use of a cervical body dissector to tent up and to progressively cut the dura above it using the blade. Careful attention is given to ensure the underlying arachnoid remains intact. At this point, the free CSF flow is observed beneath the transparent and intact arachnoid at the craniospinal level and confirms the decompression of the cerebellar tonsils. At the end of the osteodural decompression, the tonsillar tips should be clearly seen free within the new spacious cisterna magna. The dura is then stitched laterally to the muscles using a 2-0 silk suture and is left open. In patients with arachnoid changes suggesting adhesive arachnoiditis, the arachnoid should be dissected to restore CSF pathways along with the craniocervical decompression and duraplasty.

It has been widely reported in the literature that the main factor affecting the occurrence of cerebellar ptosis after FMD is a too large of a suboccipital craniectomy for the specific patient.³² In our experience, a conservative “craniectomy” is adequate to decompress the craniocervical junction in patients with overcrowding of the posterior cranial fossa and does not interfere with the occipitocervical fixation.

KEY POINTS

- The TOA is the most effective route for the treatment of the bony abnormalities that exert irreducible ventral compression of the cervicomedullary junction.
- Transmaxillary approaches are adjuncts to the TOA in patients with severe basilar invagination and limited jaw mobility.
- Transoral decompression is effective in inducing syrinx shrinkage in most patients with basilar invagination and tonsillar prolapse.
- The high risk of postoperative craniocervical instability after transoral decompression mandates posterior fixation and fusion in the same surgical session.
- Posterior craniocervical decompression is rarely required in patients with irreducible bony ventral compression of the cervicomedullary junction.

Craniovertebral junction abnormalities with hindbrain herniation and syringomyelia: regression of syringomyelia after removal of ventral craniovertebral junction compression. *J Neurosurg.* 2012;116:301-9. Patients with ventral symptomatic craniovertebral junction abnormalities have 33-38% incidence of hindbrain abnormalities. These patients can develop early or delayed neurological deterioration after primary posterior fossa decompression. Transoral decompression in irreducible pathology can allow for regression of the syrinx and patient improvement.

Dickman CA, Locantore J, Fessler RG. The influence of odontoid resection on stability of the craniovertebral junction. *J Neurosurg.* 1992;77:525-30.

Transoral decompression can exacerbate pre-existing craniocervical instability or induce pathological instability. The factors affecting the occurrence of postoperative instability are the extent of pathological bone destruction, ligamentous weakening, and operative bone removal.

Naderi S, Crawford NR, Melton MS, et al. Biomechanical analysis of cranial settling after transoral odontoidectomy. *Neurosurg Focus.* 1999;6(6).

The integrity of C1 ring has shown to be decisive in maintaining normal occiput-C2 separation. Transection of the ring of C1 during transoral approach can induce horizontal separation of lateral masses, causing cranial settling of C2 vertebral body with resultant cervicomedullary compression.

Kyphotic Cervical Deformity Correction Including Post-traumatic and Post-laminectomy Kyphosis

BIOMECHANICS AND ETIOLOGY

The normal cervical weight-bearing axis in the sagittal plane begins at the occipital condyles and should fall posterior to the vertebrae of C2–C7, passing through the middle of the C1 and T1 bodies.¹ While the exact amount of normal lordosis is somewhat challenging to define in vivo, various authors have suggested ranges between 16° and 25° in asymptomatic patients.² There are multiple methods of measuring cervical lordosis. Common methods include (1) the C2–C7 Cobb angle or (2) cervical sagittal vertical axis, the distance from the C2 plumb line to the posterior C7–T1 vertebral bodies. Normal cervical lordosis exists due to multiple structures, chief among these are the vertebral bodies and intervertebral disks. The bodies exhibit increasing size moving from a cephalad to caudal direction and the intervertebral disks, which comprise 15% of overall cervical height, have a larger anterior than posterior height. A proper sagittal vertical axis helps maintain a lordotic alignment to the cervical spine, and places 36% of loads through the anterior column versus 64% through the dorsal spinal column.³ Thus, the biomechanical demands on the posterior neck musculature are reduced and balanced by the favorable alignment that exists in the normal cervical spine.

Dorsal structures in the cervical spine have been recognized to be integral in maintaining normal lordotic posture. Among these are the cervical lamina, interspinous ligaments, facet joint capsules, and ligamentum flavum. A cervical laminectomy in the absence of fusion of a flexible spine leads to kyphosis by deranging this biomechanical balance in several ways. First, the surgical approach involves a dissection of the cervical extensor musculature, which can lead to denervation, fibrosis, or atrophy, making the muscles less capable of performing their normal duties. The muscles can be placed at further disadvantage if the attachments of the semispinalis cervicis and capitis, the primary extensor muscles of the neck and head, have been disrupted off C2. Second, a cervical laminectomy involves the removal of some of the posterior soft-tissue restraints that can act as a tension band, such as the supraspinous ligament, interspinous ligament, ligamentum flavum, and facet capsules. Third, overaggressive facet resection can lead to instability and kyphosis. Cadaveric sectioning studies have demonstrated that instability is prone to develop when >50% of a facet joint has been removed. The postlaminectomy kyphosis that occurs in the setting of aggressive facetectomy may be particularly

severe due to the combination of kyphosis and spondylolisthesis that arises and is exacerbated by compromising the normal compressive force seen by the facet joints in the cervical spine.³

This unfavorable biomechanical environment then leads to a situation in which “kyphosis begets kyphosis.”⁴ As the head translates anteriorly, the sagittal vertical axis moves anteriorly, causing additional compressive loads on the anterior column and tensile loads on the posterior column, which it is less capable of withstanding. This further compromises the mechanical disadvantage introduced by laminectomy on the posterior extensor muscles. The posterior ligamentous restraints are then also put under further tension, additionally limiting their ability to act as tension bands. Further, as the posterior musculature is elongated, there is less sarcomere overlap and the muscles become subjected to increasingly unfavorable ranges in their length–tension curves, further decreasing their action. As a result of the kyphotic deformity, the spinal cord may be draped over the kyphosis and lead to impairment in spinal cord vascularity as well as mechanical compression arising from the anterior vertebral bodies. Posterior compression of the spinal cord may also result from postlaminectomy kyphosis due to the formation of postlaminectomy membranes that can compress the dura in extension.⁵ Because of this well-studied biomechanical cycle, it is crucial to avoid performing a stand-alone laminectomy without fusion if the cervical spine already demonstrates loss of lordosis preoperatively, as the posterior anatomic structures in this scenario begin at a disadvantage and are almost certain to further deteriorate after laminectomy.

CLINICAL PRESENTATION

Many who go on to develop postlaminectomy kyphosis have initial improvement in their presenting neurologic symptoms from the decompressive operation. However, as the deforming forces progress and kyphosis develops, they may present with a variety of possible complaints. Chief among these are axial neck pain, muscular fatigue and spasm. Typically, these symptoms are mechanical and demonstrate a reasonable degree of relief at rest. As the deformity progresses beyond the elastic limitations of the spinal cord or nerve roots, myelopathy and/or radiculopathy can recur. Although the resultant foraminal narrowing may lead to presenting complaints of radiculopathy, treating surgeons should nevertheless maintain a high index of suspicion for subtle evidence of myelopathy. In the most

severe situations, kyphosis can lead to loss of forward gaze, difficulty swallowing and eating, poor hygiene in the anterior neck, and the need to prop up the neck with the hands. Respiratory problems and dysphagia are rare but reported symptoms in the more severe cases.

INCIDENCE AND EPIDEMIOLOGY

While the true incidence of postlaminectomy kyphosis is unclear, it appears to be more common in children than adults. The reported incidence of postlaminectomy kyphosis varies widely. Mikawa reported that 52% of patients demonstrated change in cervical alignment after multilevel laminectomy, with 14% developing kyphosis.⁴ Guigui noted that 31% had a change in alignment versus preoperative, with 25% having increased kyphosis.⁶ Pediatric rates of postlaminectomy kyphosis are thought to be higher due to the effects of residual growth potential in the setting of deranged force balance from the disrupted posterior stabilizing structures, negative effects of radiation therapy given to children who undergo laminectomy for tumors, the theoretically increased laxity in pediatric supporting structures, or the relative lack of spondylosis and stabilizing osteophytes in children compared with adults.⁷

Risk factors for the development of postlaminectomy kyphosis include pre-existing lack of lordosis, younger age at time of surgery, number of levels removed, especially four or more levels, laminectomized surgery involving the C2 lamina, performance of facetectomies, presence of intraspinal tumors, irradiation, and increased preoperative range of motion.^{6,8} Although laminoplasty was initially designed in order to prevent the development of postlaminectomy kyphosis, some loss of lordosis also occurs with laminoplasty. In general, however, the loss of lordosis after laminoplasty tends to be less than that seen after laminectomy and, much less commonly, of clinical significance in the properly chosen patient (Figs. 48.1A and B). Suk reported on average 5° loss of lordosis after laminoplasty, with 10.6% of patients developing an average of 12° of kyphosis. As one would predict, those who began with less lordosis (<10° preoperative) were more likely to develop kyphosis, as were those demonstrating more global flexion than extension on preoperative dynamic radiographs.⁹ Loss of lordosis with laminoplasty may be lessened by sparing C2. Takeshita found that the decrease in lordosis from C2 to C7 was 8.3° if C2 was split during laminoplasty, 5.2° with a dome-like laminotomy of C2, but only 1.5° if C2 was left completely intact.¹⁰

Figs. 48.1A and B: Postlaminoplasty K. (A) Preoperative and (B) postoperative X-rays of postlaminoplasty kyphosis. Some loss of lordosis is common after laminoplasty. Although the magnitude is generally not as severe as that seen after multilevel laminectomy, kyphosis can develop after laminoplasty as well.

The importance of preserving the attachments to C7 appears to be much less significant: Kowatari found no change in axial neck pain, Japanese Orthopaedic Association Scores, or final sagittal alignment whether the C7 attachments were preserved or not.¹¹

POST-TRAUMATIC KYPHOSIS

While the various causes of acquired cervical kyphosis are myriad and can include trauma, neoplasm, surgery, congenital deformities, skeletal dysplasias, degenerative joint disease, inflammatory conditions, and neuromuscular disorders, relatively little has been studied on post-traumatic kyphosis as a clinical entity. Post-traumatic kyphosis can arise from an injury that was either missed or incompletely treated. Additionally, pre-existing host factors may predispose a patient to development of post-traumatic kyphosis even in the setting of an otherwise innocuous-appearing injury.

Injuries that predispose to the development of post-traumatic kyphosis can be broadly grouped into anterior and posterior injuries. Vertebral body loss of height after a fracture can create tensile forces at the posterior stabilizing structures of the neck and lead to post-traumatic kyphosis. Likewise, a dorsal injury such as to the ligamentous structures or facet fracture may compromise the compressive integrity of the posterior tension band. Regardless of the

initiating event, the final common pathway of post-traumatic kyphosis results in the head and the overall weight-bearing axis shifting anteriorly.

While it has been posited that the most common traumatic injury for the development of post-traumatic kyphosis is the occult or underappreciated ligamentous injury,¹² of the well-recognized mechanisms, flexion-distraction and the so-called tear-drop (flexion-compression) injury patterns based on the Allen-Ferguson classification are the most likely to result in the development of post-traumatic kyphosis. Prompt recognition of these injuries and a properly planned treatment strategy is essential in avoiding potentially problematic kyphotic sequelae. Often times these sequelae may require multistage surgical approaches to correct.

Recent advances in spinal instrumentation combined with more broad application of screening cervical computed tomography (CT) scans in the setting of trauma are thought to have decreased the rates of inadequately treated and/or unappreciated injuries. While CT scanning as the primary radiographic tool in many trauma centers has all but supplanted plain radiography, it does not necessarily detect ligamentous injuries. Nevertheless, it is helpful in showing soft-tissue swelling and fluid that may prompt further investigation. Magnetic resonance imaging has become the gold standard in detecting posterior ligamentous injuries to the cervical spine. In addition, serial standing lateral cervical X-rays can help a clinician detect delayed post-traumatic kyphosis. Decreasing use of external orthotics such as halo vests to treat potentially unstable cervical injuries in favor of rigid segmental implants has also played a role in declining rates of post-traumatic kyphosis. Fisher et al. reported a series of 45 patients with unstable flexion-compression cervical fractures treated either with HALO vest or anterior corpectomy and plating and found a 20% rate of failure for the group treated with HALO immobilization.¹³

SURGICAL STRATEGIES FOR CORRECTION

Significant pain as well as functional and neurologic impairment can all be presenting hallmarks of post-laminectomy kyphosis. Nonoperative treatments such as physical therapy for extensor muscle strengthening may be sufficient in mild cases of kyphosis, but is unlikely to be of major benefit in those with significant, progressive

Figs. 48.2A and B: Anterior only. (A) This patient had undergone an initial ACDF at C56 and then a multilevel laminectomy. She presented with recurrent myelopathy and a mild postlaminectomy kyphosis, with cord compression at C34 and C45. (B) Status post-removal of plate at C56 and then anterior-only surgery at C34 and C45 for spinal cord decompression.

kyphosis and should not be considered a mainstay of treatment. In symptomatic patients with significant kyphosis, a surgical approach is generally required, particularly if there is myelopathy. Goals of treatment include (1) correction and fusion of deformity, ideally with a normalized sagittal vertical axis; (2) neurologic decompression; and (3) pain relief.

Flexible and Passively Correctable Kyphosis

If the deformity is flexible and passively correctable, then it may be reduced into the desired alignment and fused either anteriorly or posteriorly. The flexibility of a deformity can be ascertained from the supine CT sagittal scan with a bump placed under the patients' shoulders to induce maximal extension. Anterior-only surgery has several advantages. Anterior surgery can allow for the direct decompression of a spinal cord draped over a kyphos, avoids reoperation through a revision approach posteriorly, preserves the posterior musculature that has already been compromised, and provides height restoration to the anterior column through the use of structural interbody or corpectomy grafts (Figs. 48.2A and B). However, disadvantages of anterior only surgery include relatively less biomechanically secure fixation in the vertebral bodies versus the dorsal

elements (especially relevant in osteopenic patients) and the inability of anterior plates to restore the posterior tension band. Although anterior plates may "hold" the correction achieved through the placement of interbody grafts, they are at a relative mechanical disadvantage secondary to their action being by definition anterior to the axis of rotation of the kyphotic deformity.

Reduction in a kyphotic deformity can be performed using an anterior plate and screws after multilevel anterior interbody grafts are placed. This technique can be very powerful in correcting kyphosis. The lordotic anterior plate should be loosely secured to the proximal and distal levels. Screws can then be placed into the middle levels using the plate and screws to draw the vertebral bodies anteriorly toward the plate. The proximal and distal levels are then secured and finally tightened after the middle segments have been lagged up toward the plate. Depending on the bone quality, we generally advocate supplemental posterior fixation particularly when the anterior operation includes more than three segments.

Posterior-only surgery can also be considered in the scenario of a flexible and passively correctable kyphosis. However, in this case, it is mandatory that sufficient spinal cord decompression can be achieved through realignment and restoration of lordosis in those with neurologic compression. If this is deemed not possible, alternative strategies must be employed to achieve realignment. Posterior surgery has the advantage of generally superior fixation versus anterior plates, particularly at the ends of the construct, where pedicle screws can be routinely placed into C2, C7, and the upper thoracic spine. In addition, posterior implants are at a mechanical advantage in correcting kyphosis in that they act posterior to the axis of rotation of the kyphotic deformity. Disadvantages to posterior-only based surgery include the need for a revision approach through scar with no dural protection due to previous laminectomy, further denervation and damage to the already-compromised posterior musculature, more perioperative pain than is encountered with an anterior approach, higher wound infection rates, and limited surface areas for bone grafting and fusion. Furthermore, the lack of anterior column load sharing may make posterior constructs more prone to implant failure and screw pullout—especially at the proximal end of the construct—if the fixation is not optimal and the neck settles back toward its original kyphotic state. This is an especially important consideration in the osteopenic patient.

Figs. 48.3A and B: Anterior-posterior. (A) Elderly woman status post multilevel laminectomy who developed severe postlaminectomy kyphosis and myelopathy. (B) Due to the rigid, multilevel deformity and suspected osteopenia, a combined anterior-posterior operation was performed from C2 to T2.

Although anterior- or posterior-only surgery can generally be utilized in those with flexible deformities, other factors should be taken into consideration. In those with poor bone quality or who need a long segment fusion, an anterior approach alone may be insufficient as the screw fixation achieved in the vertebral bodies via anterior cervical plates may not be enough to counteract the deforming forces. In such cases, significant pistoning of the interbody grafts into soft endplates may occur as the spine settles back into its original kyphotic alignment. Furthermore, if a multilevel corpectomy is needed for neurologic decompression in the setting of postlaminectomy kyphosis, high rates of failure can be anticipated with anterior-only surgery due to the severe instability that develops from disconnecting the two sides of the spine with the corpectomy anteriorly and the laminectomy posteriorly.¹⁴ If bone quality is adequate and the goals of surgery can be accomplished with discectomies or short segment combination corpectomy-discectomy rather than long corpectomies, anterior-only surgery may be adequate. Should these factors not be met, a combined anterior-posterior approach is more likely to result in favorable outcomes. In addition, in cases in which the sagittal vertical axis cannot be restored, consideration should be given to maximal fixation, since major deforming forces will still be present. It is our preference to extend the fusion in to the proximal thoracic spine with pedicular screw fixation to prevent distal junctional kyphosis in the setting of postlaminectomy kyphosis.

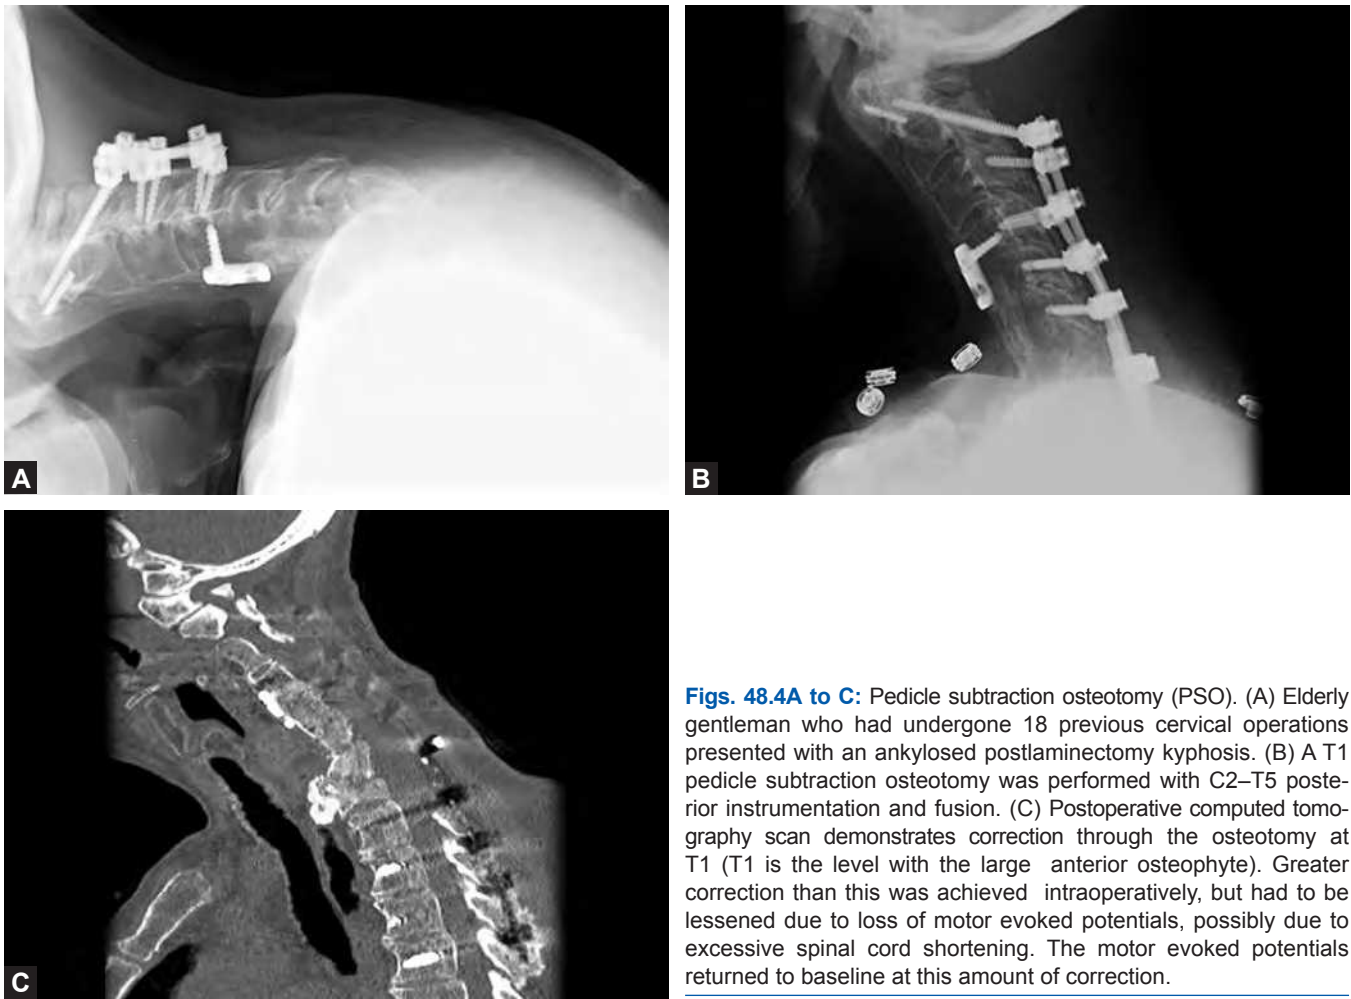

Fixed (Nonflexible) but Nonankylosed Postlaminectomy Kyphosis

If the deformity is fixed but not fused, anterior-only or combined anterior release and correction followed by posterior fusion may be appropriate depending on patient bone quality and severity of kyphosis (Figs. 48.3A and B). Again, a combined approach is best if multilevel anterior corpectomies are needed, whereas an anterior-only approach may suffice if multilevel discectomies with segmental screw-plate fixation can be performed in a patient with adequate bone quality. Inability to restore the sagittal vertical axis makes loss of correction more likely due to persistence of deforming forces, and supplemental posterior fixation should be strongly considered.

Fixed and Ankylosed Postlaminectomy Kyphosis

If the deformity is not only fixed but also fused (based on CT), then osteotomies may be required in order to achieve satisfactory correction. Osteotomies are necessary when the ankylosed segments are in such severe kyphosis that correction through the adjacent segments alone would not provide sufficient overall restoration of the sagittal vertical axis (Figs. 48.4A to C).

The approach and order of addressing the kyphosis are dictated by the location of the ankylosis. If the ankylosis is posterior, then a posterior approach should be performed first in order to osteotomize the area of ankylosis. Correc-

Figs. 48.4A to C: Pedicle subtraction osteotomy (PSO). (A) Elderly gentleman who had undergone 18 previous cervical operations presented with an ankylosed postlaminectomy kyphosis. (B) A T1 pedicle subtraction osteotomy was performed with C2–T5 posterior instrumentation and fusion. (C) Postoperative computed tomography scan demonstrates correction through the osteotomy at T1 (T1 is the level with the large anterior osteophyte). Greater correction than this was achieved intraoperatively, but had to be lessened due to loss of motor evoked potentials, possibly due to excessive spinal cord shortening. The motor evoked potentials returned to baseline at this amount of correction.

tion is obtained through the osteotomy, but supplemental anterior release and interbody grafting are often needed, followed by a second posterior approach to lock in the instrumentation (“back-front-back”). In the case of anteriorly based ankylosis, an anterior osteotomy is performed first. Should sufficient correction be achieved and bone quality be present, anterior-only surgery may be performed in this setting. Otherwise, a supplemental posterior approach is performed in order to augment the anterior correction. In patients demonstrating circumferential ankylosis, posterior osteotomies and establishment of fixation points, followed by anterior osteotomies and interbody grafting, followed by final posterior rod fixation and fusion will likely provide the best correction and final clinical result.

OUTCOMES OF SURGERY

Although the surgical management of postlaminectomy kyphosis can be challenging, high rates of successful

outcomes have been reported. Steinmetz et al. examined 10 patients treated with anterior-only correction of postlaminectomy kyphosis. The mean preoperative kyphosis measured $+13^\circ$ and was corrected to -6° of lordosis postoperatively.¹⁵ No failures were noted in this series, and loss of correction averaged only 2° at 6-month follow-up. Complications involved two cases of persistent hoarseness and one case of transient dysphagia lasting <6 months. However, the overall magnitude of kyphosis in this series was not severe. Another series evaluated patients with overall greater degrees of kyphosis who underwent anterior and posterior surgery.¹⁶ The average preoperative kyphosis was $+38^\circ$ and improved to -10° of lordosis at final follow-up. No implant failures were reported, although one patient required late revision for caudal progression of deformity. Two patients had durotomies, three had transient C5 root palsies, and another patient sustained quad-

riplegia from failure of the head-holding device. Abumi reported on the use of subaxial cervical pedicle screws in 17 patients who underwent posterior only surgery and 13 who had combined anterior and posterior surgery.¹⁷ At minimum 2-year follow-up, kyphosis improved from +28° to +5° in those with posterior-only surgery with subaxial pedicle screws, and from +31° to +0.5° in those with combined procedures also utilizing subaxial pedicle screws. Solid fusion was achieved in all patients. One patient had a pedicle fracture with root irritation that required screw removal, and another had symptomatic foraminal stenosis caused by reduction in anterior translation that required foraminotomy. No spinal cord or vertebral artery injuries occurred in this series.

CONCLUSION

The mainstay of treatment of postlaminectomy kyphosis should be prevention. As such, there are currently very limited indications for performing laminectomy alone when treating multilevel cervical myelopathy. Rather, laminoplasty or laminectomy with fusion should be considered in the majority of patients who require multilevel posterior cervical surgery as an index operation. In those who do develop symptomatic postlaminectomy kyphosis, a surgical approach is often required, particularly for those with associated myelopathy. For mild, flexible deformities, anterior surgery may be best because it allows for direct neurologic decompression, avoids a revision posterior approach, creates less perioperative pain, and recreates anterior column height. However, those with severe deformities, particularly in the setting of osteopenia, should generally undergo both anterior and posterior surgery, as the mechanical demands may exceed those provided by anterior implants alone. The exact sequence of anterior and posterior approaches will depend on the nature of the deformity, as well as the presence of associated bony ankylosis. The more severe the kyphosis, the better and more extensive the fixation should be in order to avoid complications related to implant failure. This is particularly true for patients in whom restoration of the sagittal vertical axis is either not practical or not obtained, as the presence of any residual kyphosis places great demands on the instrumentation and bone-implant interfaces. In order to prevent spinal cord injury, one should generally avoid placing tensile forces on the spinal cord by first achieving thorough decompression prior to the application

of corrective forces, and then reconstruct the spine so as to lengthen the anterior column while shortening the posterior column. With proper planning and surgical technique, the literature demonstrates that successful outcomes can be achieved.

KEY POINTS

- Normal cervical lordosis (Cobb angle from C2 to C7) ranges between 16° and 25° and is key in maintaining a proper biomechanical homeostasis in the cervical spine. Dorsal and ventral structures act to maintain cervical lordosis.
- Postlaminectomy kyphosis can present insidiously with vague complaints such as axial neck pain, muscle fatigue and spasm, radiculopathy, and myelopathy. Late findings can include loss of forward gaze, difficulty swallowing, and even respiratory problems.
- Risk factors for postlaminectomy kyphosis include pre-existing lack of lordosis, younger age at time of surgery, number of levels removed, involvement of the C2 lamina, and irradiation.
- Post-traumatic kyphosis can occur in the setting of subtle or occult ligamentous injury. Improvements in fixation techniques and implants, decreasing of external orthoses, and wider availability of CT scanning for trauma have all been thought to decrease the rates of post-traumatic kyphosis.
- Goals of treatment in postlaminectomy and post-traumatic kyphosis include correction and fusion of deformity, neurologic decompression, and relief of pain.

CERVICAL KYPHOSIS

The severely kyphotic and fixed cervical spine poses a challenge to patients and spine surgeons alike. Patients complain of progressive deformity of the cervical spine, causing both axial neck and radicular pain. As the deformity progresses, they are left unable to chew, swallow, perform hygiene or raise their eyes to see ahead of their feet—the so-called “loss of forward gaze” or “chin-on-chest” deformity, in the severe form.

The etiology of cervical kyphosis is varied. Most frequently it arises from progressive deformity from the spondyloarthropathies, most commonly ankylosing spondylitis (AS). It may also come from malunion of cervical spine fractures, degenerative spondylosis, postinfectious deformity, tumor, or from iatrogenic causes such as destabilization of the posterior elements after laminectomy. After the initial insult, the weight of the head is transferred anterior to its normal position, disrupting normal sagittal balance. With time, gravity pulls the weight of the head anterior, and bony remodeling, especially in the case of AS, leads to a progressive and fixed deformity. Although the deformity is still flexible, nonoperative therapy may involve simple modifications, such as avoidance of too many pillows to prevent loss of extension. For fixed deformities, there are limited nonoperative management options consisting mainly of activity modification, such as the avoidance of driving, to accommodate the loss of horizontal gaze in those with fixed deformity.

The aims of cervical osteotomy are to correct sagittal imbalance, reverse the kyphotic deformity, and restore the patient's horizontal gaze. Generally, osteotomy is undertaken at the cervicothoracic junction (CTJ) at the C7–T1 level, though correction can take place at any level of the cervical spine. The CTJ lends itself as the ideal location for osteotomy and correction for a number of reasons. First, the cervical spinal canal progressively widens from cephalad to caudad, becoming widest at C7–T1. This affords itself to posterior osteotomy, as the procedure requires extension of posterior elements, which can buckle the posterior dura, leading to stenosis and spinal cord injury. Second, 90% of the time, the vertebral artery (VA) enters the transverse foramen at the C6 level. Osteotomy caudad to this level removes the danger of injury to the VA during the osteotomy as the VA lays anteriorly. Finally, in the event of spinal cord injury during either osteotomy or extension of the osteotomized segments, injury should theoretically allow the patient to maintain use of upper extremities when compared to midcervical spinal cord injuries.

PREOPERATIVE CONSIDERATIONS AND EVALUATION

Patient selection is critical for success. Contraindications to cervical osteotomy include patients with flexible deformities and those with fixed deformities not severe enough

Figs. 49.1A to D: (A) A patient with ankylosing spondylitis presented with progressive loss of forward gaze with a chin–brow vertical angle of 30° . (B) Preoperative lateral upright radiograph shows global positive sagittal imbalance due to thoracic kyphosis with loss of lumbar lordosis. (C) Postoperative lateral upright radiograph after L3 pedicle subtraction osteotomy shows correction of the global sagittal imbalance. (D) Follow-up photograph shows improvement in the sagittal balance and forward gaze.

to warrant such a large undertaking. Flexible deformity can be treated with multilevel anterior or combined anterior/posterior procedures followed by segmental fixation. Many patients with cervical kyphosis have deformities in the lumbar and thoracic spine, as well as hip contractures that may be contributing to the sagittal imbalance and loss of horizontal gaze. A cervical kyphosis of $<30^\circ$ generally does not warrant cervical osteotomy correction; in such a patient, one has to assess the global sagittal imbalance and evaluate the lumbar spine and the hip joints for their contribution in the disability associated with sagittal imbalance. Correction of these deformities should be attempted before undertaking an osteotomy at the cervical spine. Deformity in the hips is generally addressed before lumbar or thoracic spine, and lumbar and thoracic deformities are corrected before the cervical spine (Figs. 49.1A to D).

Poor candidates include those unable to be positioned in the method of the surgeon's choice. Prone positioning may be problematic for patients with pulmonary limitations. Other relative contraindications include bleeding disorders, those medically unfit for surgery, and those unable to participate in postoperative rehabilitation.

As with any spine surgery, medical comorbidities should be optimized with the assistance of the appropriate medical specialists. Severe thoracic kyphosis may limit pulmonary function, and increase the risk for anesthesia and positioning in the prone position. History of trauma, infection, cancer, or previous surgery should be elicited. History should focus on limitations of deformity. Patients

unable to chew and swallow may be malnourished, which may require dietary optimization before surgical procedures to avoid pseudarthrosis and wound healing complications. Nonsteroidal anti-inflammatories should also be terminated to avoid risks of excessive bleeding and risks of delayed fusion. Detailed neurologic examination may demonstrate preexisting neurologic injury, including C8 nerve root and possible myelopathy, though this has been shown to be relatively uncommon in kyphotic deformity.

Clinical evaluation of the sagittal imbalance starts with examination of the patient while standing with knees and hips fully extended in order to eliminate any compensatory knee or hip flexion that may mask a severe deformity. The patient is then examined in the sitting position; if the trunk appears with good balance in relation to the pelvis, then hip flexion contracture may be the cause and this can be demonstrated with the Thomas test. If the forward displacement of C2 in relation to the pelvis remains in the sitting position, the patient is then assessed in the supine position. When the deformity is localized to the lumbar spine, patients will be able to lie with their shoulders on the table. If the head and upper thoracic spine remains elevated from the table, fixed deformity in the cervical and/or thoracic spine is likely.

Chin brow to vertical angle (CBVA) is measured in the standing position with knees and hips fully extended. This is best measured with photography (Figs. 49.1 and 49.2). A vertical line is drawn perpendicular to the ground. A separate line connects the chin to the brow. The intersection

Figs. 49.2A to D: (A) A patient with ankylosing spondylitis presented with chin-on-chest deformity and a chin-brow vertical angle of 86° . (B) Preoperative lateral upright radiograph shows cervical kyphosis. (C) Intraoperative lateral upright radiograph after C7–T1 posterior extension osteotomy shows correction of the cervical kyphosis. (D) Follow-up photograph shows improvement in the sagittal balance and forward gaze.

angle is the CBVA, and in the normal the patient should be at 0° . Severe cervical kyphosis can lead to deformity exceeding 90° . Preoperatively, the surgeon should aim for a CBVA of 10° of flexion. The CBVA should not be corrected beyond 0° to allow for appropriate gaze both upward and downward. Overcorrection leaves the patient with an unsteady gait and renders the patient unable to walk downstairs or participate in daily social situations.¹

Plain radiographic findings determine the site of osteotomy and the amount of correction expected. Radiographic evaluation should include full 36-inch length cassette films to evaluate for deformity in the lumbar, thoracic, and cervical spine. These films should be upright. Flexion and extension views should be obtained. The area of the planned

osteotomy can be templated on the X-ray film to estimate amount of correction expected. Both C2–C7 and C7–S1 plumb lines should be measured to assess for the regional and global sagittal imbalance and determine whether it will be corrected with the chosen site of osteotomy. Computed tomography (CT) scan is useful to evaluate bony anatomy, including vertebral body size, areas of previous laminectomy, and osseous landmarks for potential instrumentation. Magnetic resonance imaging (MRI) scan supplements the CT scan and plain radiography. MRI may reveal areas of spinal cord compression that may need to be addressed at the time of surgery. Aberrations in VA anatomy are also revealed on MRI or CT angiogram. It may also reveal areas of potential spinal cord tethering that could complicate the closing of the osteotomy site.

OSTEOTOMY OPTIONS

Posterior Extension Osteotomy

Osteotomy of the cervical spine was pioneered shortly after Smith-Petersen and others described lumbar osteotomy.² Urist reported a single case of a patient with AS with severe kyphotic deformity and a chin-on-chest deformity.³ The patient's flexion deformity necessitated that the procedure be performed under local anesthesia in the seated position with the patient awake. Neurologic monitoring was facilitated by the patient's awake status. The posterior osteotomy was performed at the CTJ. The procedure began with a partial laminectomy at C6 and T1, complete laminectomy at C7, followed by wide resection of the C7 lateral masses. The majority of the C7 pedicles were also taken down. The patient was briefly anesthetized, and the posterior osteotomy was closed with osteoclasis of the anterior vertebral body with gentle extension of the neck. No bone graft was used. The patient was placed in a spinal brace that supported the chin and neck and allowed for gradual manual correction. After final correction over the course of some weeks, the patient was placed in a plaster Minerva for 12 weeks and then encouraged to wear a cervical collar indefinitely when in public. Final correction angle was 64° and the patient's horizontal gaze was restored. He reported only transient, relatively minor, neurologic complications.

Simmons modified the posterior extension osteotomy described by Urist, continuing to use the seated position and local anesthesia rather than prone positioning with general anesthesia.⁴ A halo vest with adjustable rods was used for 4 months followed by soft collar for 2 months. Local bone graft was used to facilitate fusion without the use of internal hardware. Postoperative CT scans were used to assess bony fusion. They reported CBVA correction from an average of 81° to 4° postcorrection in one early group. The second group had average CBVA correction from 49° to 12°. They experienced over 95% fusion rate at the osteotomy site.

Using the posterior extension osteotomy carries with it advantages and disadvantages. Monitoring neurologic status on an awake patient allows for the most accurate observation of any neurologic injuries during surgery, eliminating the false negatives and false positives of somatosensory-evoked potentials (SSEP) and transcranial motor-evoked potentials (MEP) monitoring. Advocates of avoiding internal fixation argue that the use of the halo postreduction allows for correction of deformity outside the operating room, if necessary. In the event of postoperative neurologic compromise, traction via the halo may be

applied to reduce pressure on the offending nerve root. Avoiding internal fixation also significantly shortens operative time and reduces blood loss. When fusing one single vertebral level, the surgeon can avoid long fusion masses and lever arms. This is especially important when considering the poor bone quality in patients with AS when attempting instrumentation. Instrumentation will also be more difficult given the loss of bony landmarks due to either AS or previous trauma or surgery. High rates of fusion have been reported with halo fixation as shown by Simmons, who reported fusion rates >95%. With modern halo vest application, rates of postoperative displacement occur only rarely.

Disadvantages to the posterior extension osteotomy originate from the lack of internal fixation, method of osteotomy, and patient positioning. Halo vest fixation requires a minimum of 4 months of immobilization postoperatively to allow for stable fusion mass. Internal fixation may obviate the need for the halo, though some surgeons support the use of the halo even in the presence of internal fixation due to the poor bone quality, usually found in this patient population. Osteotomy of the posterior elements requires osteoclasis of the anterior column during extension at the osteotomy site. In AS, osteoclasis requires little force during osteotomy closure. In the non-AS, closure of the osteotomy site may require excessive force, leading to uncontrolled osteoclasis and the risk of neurologic injury. In addition, osteoclasis of the anterior elements frequently leaves an anterior void at the fracture site. This can lead to instability, potentially leading to subluxation and potential neurologic compromise in the postoperative period. There is also a theoretical risk of air embolism when performing upright surgery due to negative pressure.

Pedicle Subtraction Osteotomy

Recent reports have described the successful use of a pedicle subtraction osteotomy (PSO) for correction of cervical kyphosis.⁵⁻⁷ The procedure is typically done in the prone position under general anesthesia. With the patient asleep, neurologic monitoring is accomplished via SSEP, MEP, and electromyography. The osteotomy is generally approached at C7-T1, though it may be centered higher if required. A standard posterior approach is used, exposing the spinous processes, lamina, facets, and transverse processes. Instrumentation is performed either before or after resection of the osteotomy, with most authors encouraging fusion of at least three spinal levels above and below the osteotomy level. Where possible, pedicle screws in C7 and

upper thoracic spine and lateral mass screws between C3 and C6 are inserted. Instrumentation may have to include pedicle screws in C2 or even the occiput. If high thoracic kyphosis is present, instrumentation should include the apex of the curve to prevent distal junctional kyphosis. The posterior elements are removed in a similar fashion as in the posterior extension osteotomy. The pedicles are then removed using subsequently larger pedicle taps, followed by decancellation of the vertebral body. The posterior and lateral cortices of the vertebral body are then removed with rongeurs and osteotomes. The surgeon should ensure that the cranial and caudal surfaces of the vertebral body (VB) osteotomy sites are level to avoid creation of a coronal plane deformity. With the near circumferential release of the bone, extension of the osteotomy is possible. As the vertebral body has been removed, closure of the osteotomy site centers anterior to the spinal cord. Rods connect the pedicle and lateral mass screws, and secure the spine in the corrected extended position. Some authors advocate using a temporary flexible rod to unilaterally hold the osteotomy in place to stabilize the cervical spine both before and after reduction. The flexible rod is replaced with the final rod after the contralateral rod is tightened. Bone graft is used to obtain fusion. A halo vest or a hard collar is used for temporary support as the fusion heals.

Deviren et al. reported results for PSO in the cervical spine for kyphosis. Preoperative regional cervical sagittal imbalance was 7.9 cm.⁶ This was corrected to 3.4 cm immediately after surgery, and no loss of reduction was noted on follow-up. The mean PSO correction was 19°, and the mean CBVA correction was 36.7°. There were no reports of pseudarthrosis.

Advocates of the PSO argue that closure of the osteotomy site requires less force and is more controlled with the osteotomy being taken just short of the VB anterior cortex. With the axis of rotation being far anterior at the anterior cortex, the anterior column is not lengthened. Increased cortical contact at the VB osteotomy sites also leads to more stability. Internal fixation may eliminate the need for long-term halo vest application and allows the patient greater mobility. Instrumentation also holds a more rigid construct, lessening the chances of postoperative loss of reduction and possibly improving fusion rates to avoid the need for reoperation. General anesthesia allows for a more controlled surgical theater in the event of adverse outcome given the difficult airway that severe kyphotic deformities can present for anesthesiologists.

Combined Anterior and Posterior Approach

Sasso et al.⁸ describe approaching the osteotomy site both from anterior and posterior exposures. Their technique addresses the anterior gapping, found commonly with the posterior extension osteotomy using osteoclasia to close the osteotomy site. The procedure is performed under general anesthesia, with the first portion being the anterior approach. Some deformities were too severe to allow both anterior and posterior dissections. In these cases, only posterior osteotomies were performed. A standard Smith-Robinson approach was used, and any abnormal ossification was taken down in a controlled fashion. A discectomy was performed at the level of the planned osteotomy. This creates the desired “wedge.” To assist with the posterior approach, the contralateral pedicle (e.g. left pedicle if using a right-sided Smith-Robinson approach) is visualized and resected. If working above the C7-T1 level, the transverse foramen is dissected out to untether the VA during osteotomy closure. When working at C7-T1, this is unnecessary. After the appropriate dissection, the anterior incision is provisionally closed with staples while the posterior portion of the operation is undertaken. The patient is then turned to the prone positioning. The standard posterior approach is then used to expose the desired level of fusion. Pedicle screws in C7 and the upper thoracic spine and lateral mass screws between C3 and C6 are inserted. Before the osteotomy, flexible, hollow stainless steel rods are placed for provisional fixation, preventing subluxation during the osteotomy. After appropriate hardware is placed, the osteotomy is performed. A posterior wedge osteotomy is performed by removing the inferior spinous process, lamina, and inferior portion of the articulating facet of the cephalad vertebral level. At the osteotomy level, the spinous process, lamina, facet joints, and the remaining pedicle are removed. Any remaining transverse foramen is also removed while protecting the VA. The caudal spinous process and portions of the lamina are then removed. One of the surgeons then leaves the surgical field to help control closure of the osteotomy. The remaining, scrubbed surgeon monitors the closure of the posterior elements, dura, and visible nerve roots while SSEP and MEP are monitored. The provisional rods prevent sudden movements during closure and allow for a safer correction. When reduction has been completed, provisional rods are replaced with permanent rods, decortication and bone grafting is completed, and the posterior wound

is closed. The anterior gapping is then addressed as the patient is once again turned supine and tricortical iliac crest bone grafting is placed with an anterior locking plate. After closure, the patient is placed in a Miami-J collar.

Compared to isolated posterior procedures such as the posterior extension osteotomy and the PSO, the so-called “540” procedure offers the advantage of secure fixation both anteriorly and posteriorly. This may offer an advantage in achieving higher rates of fusion and in preventing subluxation of the osteotomy site. It also addresses the anterior gapping seen in isolated posterior extension osteotomies. The anterior release and discectomy may be of benefit when operating on the patient with non-AS where anterior bone is not brittle and may require some force to obtain osteoclasia. Anterior release in these situations may allow for a more controlled closure of the osteotomy site. The most obvious limitation of the “540” is repositioning of the patient with an unstable spine due to osteotomy. However, the authors do not report any complications related to positioning either in final outcomes or with intraoperative neuromonitoring. The anterior approach alone poses challenges in patients with severe kyphosis in gaining the appropriate exposure. Furthermore, the frequently ossified anterior spine in the patient with AS distorts normal anatomy. In these cases, one must frequently rely on posterior anatomy such as the spinous processes to identify the correct operative level.

Flexion Osteotomy of the Cervical Spine

Sengupta et al.⁹ reported a case of a 44-year-old woman with a global kyphotic deformity caused by AS who underwent corrective lumbar osteotomy. Ten years later, she experienced further development of the kyphosis, predominantly at the thoracic level, with resultant restriction of forward gaze. A thoracic corrective osteotomy was performed, which resulted in an upward deviation of her visual field. A flexion osteotomy was then performed at C7-T1. This case report highlights the importance of preoperative planning before performing spine osteotomy. When dealing with patients with fixed kyphotic deformity, one has to consider the effect of the osteotomy on the gaze angle in addition to the global sagittal balance.

POSTOPERATIVE MANAGEMENT

Initial postoperative management varies as determined by the type of osteotomy and fusion chosen. Osteotomies performed without instrumentation require halo vest

immobilization for a recommended 4-month period. Immediate postoperative X-rays and frequent office visits are used to ensure that reduction is maintained. In the event of neurologic deterioration, radiographs should be obtained to ensure alignment is unchanged. Longitudinal traction may be applied through the halo vest to relieve compression of neurologic structures. Before removal of the vest, clinical evaluation is supplemented by radiographic evidence looking for fusion, including a CT scan to assess for union. Once fusion has been established, a rigid cervical collar is continued for 2 months more.

Patients with internal fixation are placed for 3 months in either a rigid collar, such as a Miami-J, or a halo vest depending on the quality of the fixation. Some authors routinely use CT scans to assess for fusion at 1 year. Unlike the use of halo vest immobilization without instrumentation, postoperative adjustments are not possible should neurologic deterioration occur.

OUTCOMES

Urist wrote that his procedure on his patient had a “profound change in her appearance and in her psychological outlook upon life.”³ Indeed, extension of the cervical spine to the near-anatomic position typically results in good to excellent outcomes. Etame et al. reviewed seven studies focusing on the patient with AS and showed that horizontal gaze was restored in all patients. The method of osteotomy varied between studies, as did the method of fixation with internal and external fixation both being employed.¹⁰ All osteotomies were performed at the C7-T1 level. The CBVA was measured preoperatively in these studies, ranging on average, from 41° to 56°. The postoperative CBVA in these same studies ranged, on average, from 4° to 12°. As previously mentioned, care should be taken to avoid overcorrection of the CBVA as this can negatively impact outcomes. Overcorrection may even require reoperation with a flexion osteotomy.

McMaster reported the results of 15 patients with AS treated by an extension osteotomy at the C7/T1 level. The operation was performed under general anesthesia, with the patient in the prone position and wearing a halo jacket.¹¹ Three had internal fixation using a Luque rectangle and wiring. Before operation the mean cervical kyphosis was 23°; this was corrected to a mean of 31° of lordosis, a mean correction of 54°. All the patients were able to see straight ahead. One patient with normal neurological status soon after operation became quadriparetic after 1 week; two others had unilateral palsy of the C8 root, which improved.

There was subluxation at the site of the osteotomy in four patients, and two of them developed a pseudarthrosis that required an anterior fusion.

Samudrala et al.⁷ reported results of eight patients using PSO in a series without patients with AS. All eight patients had correction of horizontal gaze. CBVA preoperatively, on average, measured 36.4° and postoperatively averaged 4°. All patients had internal fixation, with fusion of a minimum of three levels above and three levels below the site of osteotomy. Deviren et al. reported on 11 cases utilizing the PSO technique. The average CBVA correction measured 36.7°, with all patients reporting correction of horizontal gaze.⁶ Simmons et al.⁵ reported the long-term outcomes of a cervical extension osteotomy for AS in 131 patients. They achieved a good correction with the average preoperative and postoperative angles of 56° and 4°, respectively. Two patients had significant neurologic complications, and 18 patients had transient C8 radiculopathy. The incidence of pseudoarthrosis was 4.6%, with 6 patients requiring revision surgery. While no studies compare the outcomes of different types of osteotomies, all studies report correction of the CBVA.

Pain alone is not an indication for a cervical osteotomy. However, a few studies measured pain both preoperatively and postoperatively at final assessment. Belanger et al.¹² reported that 21 of the 24 patients reported improvement in pain. Final assessment showed that 10 of the 24 had no pain, 13 only had mild pain, and 2 complained of moderate pain. No patients complained of severe pain at final follow-up, compared to seven with severe pain before corrective surgery.

■ COMPLICATIONS

Cervical osteotomy, regardless the method of fixation or osteotomy type, carries with it risks of complications. Common complications include halo pin tract infections and wound complications, similar to other posterior cervical procedures. Nonunion is uncommon, but may occur in 5–10% of patients. Treatment requires reoperation with revision fusion. Fewer nonunions have been seen in the limited cases series utilizing PSO and instrumentation, though these reports involve far fewer patients than those reported on by Simmons et al.

Intraoperative bleeding is common, often exceeding 1 L. Instrumented fusions tend to have larger amounts of bleeding. Vascular injury to the VA is possible. Osteotomy below C6 lessens this risk as the VA enters the transverse

foramen most frequently at C6. Carotid artery injury from traction during closure of the osteotomy site has been reported.

Overcorrection or undercorrection of the chin-brow vertical angle tends to contribute to poor outcomes. Undercorrection leads the patient in a similar position as preoperatively. Overcorrection leads to an upward gaze, preventing the patient from performing basic tasks such as walking downstairs, working on a computer, or participating in conversations.

Neurologic injury most frequently involves injury to the nerve root at the osteotomy level, most commonly the C8 nerve root, though this finding is usually transient. Wide decompression of the neuroforamen lessens the risk of radiculopathy. Quadriplegia and paraparesis are rare complications, especially in more recent case series when compared to earlier reports. Careful, wide decompression of the osteotomy site and controlled closure of the osteotomy may lessen the risk of injury to the spinal cord. Osteotomy at the CTJ provides a wider cross-sectional area than higher cervical levels for osteotomy closure. Loss of reduction postoperatively may prove catastrophic and may lead to radiculopathy, paraparesis, quadriplegia, or even death. Pedicle subtraction osteotomy and internal fixation offer theoretical advantages in avoiding this complication by creating a more rigid construct, though loss of fixation has been seen in instrumented osteotomies.

■ AUTHORS' PREFERRED METHOD, AVOIDING PITFALLS, AND COMPLICATIONS

1. *Patient selection:* Clinical and radiological evaluation of the regional and global sagittal imbalance and preoperative optimization of medical comorbidities are essential for good outcomes.
2. *Seated position:* Inpatients with chin-on-chest deformity performing the surgical procedure in the sitting position allows appropriate positioning of the patient and gives the surgeon good control of the head-neck axis (Figs. 49.3A to C). As most of the patients with AS have large fixed deformities, prone positioning is sometime technically challenging.
3. *Correct level of osteotomy:* Intraoperative radiographic confirmation of the correct level of surgery at C7–T1 is important as if the osteotomy is done below T1 in error, the rigid thoracic cage will not allow any correction.

Figs. 49.3A to C: (A) Intraoperative photograph shows the patient in the sitting position with the halo vest and overhead traction on the halo ring to stabilize the head. (B) Intraoperative photograph shows the neck is brought back in a gentle extension arc by the surgeon, not pulled straight backward, to correct the kyphosis by osteoclasia of the anterior column after the osteotomy completion. (C) Intraoperative photograph at the end of the surgical procedure shows correction of the cervical kyphosis and the gaze angle.

Fig. 49.4: Intraoperative photograph, patient head is at the top, shows wide laminectomy at the level of the osteotomy as well as the caudal and cephalad levels, C7-T1 bilateral lateral mass resection, and foraminotomy.

4. *Adequate decompression:* Wide laminectomy at the level of the osteotomy as well as the caudal and cephalad levels is an important step to allow ample room for the spinal cord after the deformity correction, to avoid spinal cord injury. Bilateral C7-T1 foraminotomy is essential to avoid C8 nerve root palsy after surgery (Fig. 49.4).
5. *Instrumentation:* If used, multiple levels must be included C2-C3 down to T2 to avoid early hardware failure and loss of correction.
6. *Postoperative immobilization:* A halo vest for 3 months, followed by 6 weeks in a cervical rigid collar, may be deemed necessary, even if instrumentation is used to avoid failure of internal fixation and loss of correction, as patients with AS have extremely osteopenic bone and the spine is completely rigid cephalad and caudal to the osteotomy site that creates a significant lever arm.

SUMMARY

Patients with severe fixed kyphotic cervical spine chin-on-chest deformity face major difficulty in their daily activities such as swallowing, performing hygiene, and loss of forward gaze. The goals of the cervical osteotomy are to correct the sagittal imbalance, reverse the kyphotic deformity, and restore the patient's horizontal gaze. Preoperative evaluation is paramount for appropriate patient selection. History should focus on limitations of deformity. Many patients with cervical kyphosis have deformities in the lumbar and thoracic spine, as well as hip contractures that may be contributing to the sagittal imbalance and loss of horizontal gaze. Clinical evaluation to determine the level causing the deformity is essential. Generally, the osteotomy is undertaken at C7-T1 level. Methods of anesthesia, general or local, to operate in a sitting or prone position, type of osteotomy, to use or not use instrumentation—are all debatable and depend solely on the surgeon's preference as each modality has its advantages and disadvantages. No matter what technique is used one should avoid over- or undercorrection. It is recommended to correct to 10° of flexion.

KEY POINTS

- Patients with severe fixed kyphotic cervical spine deformity face major difficulty in their daily activities such as swallowing, performing hygiene, and loss of forward gaze.
- Cervical osteotomy can result in profound change in the patients' appearance, daily functions and in psychological outlook upon life.
- Clinical and radiological evaluation of the regional and global sagittal imbalance and preoperative optimization of medical co-morbidities are essential for good outcomes.
- No matter what technique is used one should avoid over or under correction. It is recommended to correct to 10° of flexion.

INTRODUCTION

Whiplash injury to the neck and cervical spine and whiplash-associated disorders (WAD) continue to represent clinical challenges for evaluation and treatment as well as costly public health problems. One estimate of the minimum annual incidence of WAD in North America and Western Europe is 300 per 100,000 inhabitants.^{1,2} Major obstacles to care include the characteristic absence of diagnostic findings on imaging studies as well as the frequent potentially complicating issues of active litigation or employment/insurance compensation. Over the past two decades, advances have occurred in the understanding of both whiplash injury biomechanics and potential pathoanatomy. Unfortunately, these advances have failed to translate into measurable improvements in patient outcome. Approximately, half of affected patients report continued symptoms for months to years following injury and up to 30% report moderate-to-severe pain and disability.^{3,4} Ongoing controversy surrounds two specific issues: (1) the role of tissue injury in etiology of WAD and (2) the effect of litigation or workers' compensation on natural history and response to treatment.

The term “whiplash” was first used in 1928 by Dr Harold Crowe, an orthopedic specialist, while reporting on eight cases of neck injuries resulting from traffic accidents.⁵ He later expressed regret at his original use of the term that had become widely adopted by the general public and many physicians to imply a specific disease or injury rather than simply a description of motion, which had been his

original intent. The first published medical use of the term “whiplash” came in a 1945 review of cervical spine injuries in the *Journal of the American Medical Association*.⁶ For many years, progress in research and clinical care was hindered by the absence of formally defined terms. The Quebec Task Force on Whiplash-Associated Disorders established the following practical definitions that will be utilized for the purposes of this review: “Whiplash” is defined as “an acceleration-deceleration mechanism of energy transferred to the neck which may result from rear end or side impact, predominantly in motor vehicle collisions, but also from diving accidents, and from other mishaps.” Actual bone or soft tissue injury resulting from such energy transfer is considered “whiplash injury.” The wide variety of clinical symptoms and signs associated with such an event is referred to as “whiplash-associated disorder.”¹

MECHANISM OF INJURY AND RISK FACTORS

Whiplash injury is most frequently observed following rear-end motor vehicle collision.⁷ The term “whiplash” derives from early observations that resulting acceleration of the head exceeds acceleration of the torso that in turn exceeds acceleration of the pelvis—a mechanism which resembles a cracking whip. Early rear-end crash tests demonstrated large neck extension moments resulting from the head rotating backward over low seatbacks. This finding triggered US federal legislation mandating head

restraints in new vehicle construction and has resulted in a significant reduction in the frequency of whiplash injury.

Despite the introduction of head restraints, whiplash injuries continue to occur with relative frequency, indicating the persistence of other potential mechanisms besides simple neck extension over low seatbacks. More recent studies have recognized a complex pattern of spinal segmental motion that has been referred to as “retraction” and which appears to be responsible for generating potentially injurious forces during rear-end collisions. Following impact, forward acceleration of the seatback leads to acceleration of the torso, while inertia of the head resists forward motion. “Retraction” refers to the horizontal translation between upper and lower cervical vertebrae during this stage. As the upper cervical spine accelerates the skull base forward, the head extends until there is contact with the head restraint. Following contact and compression of the seatback and head restraint, the torso and head are propelled forward until the shoulder belt engages to arrest forward torso motion, resulting in forceful head and neck flexion.

Retraction is characterized by rapid transition through three distinct spinal configurations. Prior to impact, the cervical spine is normally lordotic. Shortly after impact, the lower cervical spine is accelerated forward relative to the upper cervical spine resulting in lower cervical spine extension and upper cervical spine flexion. With further forward translation of the lower cervical spine, the upper cervical spine is pulled into extension with head extension occurring as well. Awareness of this more sophisticated injury mechanism has aided in the development of additional safety features such as active head restraint and the Whiplash Protection System.⁸ Such improvements have reportedly been associated with further reductions in rates of whiplash injury.⁹⁻¹¹

Head and neck orientation at the time of impact appears to be a determining factor in the nature and severity of whiplash injury. Head and neck rotation at the time of impact has been associated with increased rates of multiple injuries and development of chronic symptomatology.¹² One magnetic resonance imaging (MRI)-based study has suggested that this position poses potential greater risk of injury to the transverse atlantoaxial and occipitocervical alar ligaments.¹³ It has also been proposed that pre-existing cervical spine malalignment, particularly reversal of normal anatomic lordosis, may also increase the risk of serious injury possibly due to pretensioning of the zygapophysial joint capsular ligaments and interspinous and supraspinous ligaments.^{14,15}

It is unclear if there are other patient-specific risk factors for WAD. Multiple studies have suggested that female gender may be a risk factor for both acute whiplash injury and more chronic WAD, although this association has not been firmly established.^{1,16-22} It has been proposed that this finding may be because that women tend to have more slender necks, and their cervical spines may therefore have less inherent stability and resistance to injury.²³ Studies have reported conflicting findings with respect to the effect of age and general health on risk of injury.

Reflex contraction of neck muscles during rear-end collisions may be a determining factor in whiplash injury. Studies have demonstrated consistent patterns neck muscle activation during rear-end collision, but there appears to be significant variation among individuals. Typically, the sternocleidomastoid muscles are activated early, contracting within 60–90 ms of impact and relaxing within 150–200 ms.²⁴⁻²⁶ The posterior paraspinal muscles are activated within 10 ms of the sternocleidomastoids but typically remain activated following rebound off the head restraint.²⁴ Crash simulations have demonstrated that relatively large forces are transmitted to the head and neck in even low-speed collisions. With a velocity change of only 8 km/h, external forces to the back of the head from the head restraint have been measured up to 500 N.²⁷ Whether reflexive neck muscle contraction mitigates or aggravates injury from these forces or whether variation in muscle behavior affects risk remains unclear.

■ TISSUE INJURY

The absence of readily discernible tissue injury on diagnostic imaging studies remains one of the most frustrating aspects of evaluation and treatment of whiplash injury for both patient and practitioner alike. Despite ongoing neck pain and stiffness as well as an often baffling assortment of associated symptoms such as headache, dizziness, ill-defined visual disturbance, and varying distributions of radiating pain, batteries of diagnostic tests generally fail to reveal any clear abnormality. Increasingly, modern medical practice has become laboratory and test based, so when radiographs and advanced imaging do not demonstrate anticipated pathology such as a fracture or herniated disk, persistent pain and disability are often inappropriately attributed to patient malingering. Nevertheless, significant progress has been made over the past two decades in terms of identifying actual anatomic sources of pain in many if not most sufferers of whiplash injury and WAD.

Zygapophysial (Facet) Joint Injury

Of all the anatomic structures implicated in whiplash injury, the zygapophysial joint has been the target of greatest investigation, and currently, injury to these joints appears to be the most common treatable source of pain in affected patients. Findings from postmortem studies of motor-vehicle accident victims have limited applicability to whiplash injury, given the much different energy levels and vastly different injury mechanisms involved. Nevertheless, autopsies have reported frequent occurrence of nonlethal tissue damage that would be difficult to identify on conventional medical imaging, including varying degrees of both intervertebral disc and zygapophysial joint injury. Observed joint injury patterns range from intra-articular hemorrhage, cartilage fracture, and subchondral bone fracture to more readily diagnosable articular process fracture.^{28,29} These findings suggest at least the possibility that actual gross tissue injury may occur in whiplash injury that is below the threshold of detection of widely available imaging modalities.

Additional support for the occurrence of zygapophysial joint damage during whiplash injury comes from biomechanical studies. In normal healthy volunteers and simulated rear-end collision, cineradiography demonstrated S-shaped deformation of the cervical spine as previously described but also an important upward directed axial load as the torso is accelerated toward the head.³⁰ Following rear-end collision, extension of the lower cervical spine, particularly at the C5–C6 level, is characterized by a nonphysiologic and abnormally high instantaneous axis of rotation. This mechanism may lead to both anterior annular rim avulsion injury as well as direct impaction of the zygapophysial joints with impingement or crush injury of synovial tissue or intra-articular meniscoids as well as cartilage and bone injury.²⁹ Following initial cervical extension and rebound off the head restraint, cervical flexion motion may exceed tolerance limits of the posterior ligaments and joint capsules, and result in a distraction strain injury to these structures. Recently, stretch injuries to the facets have been studied in animal models of whiplash, and the results have supported the theory that this mechanism can generate whiplash-associated pain.^{31–37}

Intervertebral Disc Injury

In the vast majority of patients with whiplash injury or WAD, no clear intervertebral disc injury is apparent. Magnetic resonance imaging evaluation commonly reveals

nonspecific degeneration of disc tissue as well as one or more disc protrusions but nothing that appears to represent an acute injury. One consideration is that MRI evaluation is generally performed later after several weeks or even months and only when expected recovery has not occurred. It is well known that most acute disc herniations spontaneously resolve and the appearance of acute disc disruption may also rapidly improve. In some cases, delayed imaging may not have been performed early enough to demonstrate such injuries. Another complicating issue is the prevalence of asymptomatic disc protrusions and herniations in the general population even in the absence of any history of trauma. Therefore, it cannot be simply assumed that whiplash injury-associated pain and symptoms are due to a disc abnormality visualized on MRI.

Even in the absence of clearly identifiable gross tissue disruption or herniation on MRI studies, subtle but painful disc injury may still be a factor in many patients suffering from whiplash injury and WAD. Biomechanical studies of low-speed collision have demonstrated extension moments and associated strain that on average appears to affect maximally the level of the C4–5 disk.^{38,39} With increasing impact energy, progressively greater strain is observed extending to neighboring disks.

Muscle Injury

Following whiplash injury, patients are often evaluated in the emergency department or by their primary care physician and diagnosed with “cervical strain injury.” In addition to diffuse neck pain and stiffness, neck muscle palpation often elicits tenderness that is interpreted as representing benign and nonspecific muscle tissue injury. Again, MRI evaluation is generally unrevealing and does not demonstrate any gross muscle tear or hematoma formation.

One series of studies, however, has suggested that fatty infiltration of both cervical spinal flexor and extensor musculature may be observed on MRI during the subacute phase in many patients and that this finding appears to be associated with more painful and disabling whiplash injury and may also be a marker for patients at risk for transition to chronic WAD.^{40,41} The same investigators reported consistently greater cross-sectional area measurements of the multifidus muscle in WAD patients and suggested that this phenomenon may represent pseudohypertrophy of the muscle due to higher fat content.⁴² Fatty infiltrates appear to evolve between 4 weeks and 3 months following injury but were not observed in patients with mild or

resolved symptoms. Both disuse and traumatic denervation have been proposed as explanations for these findings, but so far clinical evidence strongly supporting either mechanism remains lacking.

Although neck pain and stiffness are the most common presenting symptoms, dizziness, unsteadiness, and blurred vision are the next most frequent symptoms and may be reported in as many as 70% of patients with WAD.⁴³ The symptom of dizziness, in particular, may represent a risk factor for the development of WAD.⁴⁴ Despite widespread prevalence, no specific pathoanatomic correlates have been identified. In some patients, there may be damage to the peripheral vestibular system, as benign paroxysmal positional vertigo has been observed in as much as half of WAD patients with these symptoms.^{45,46} In a small percentage of patients, prefrontal cortex, brainstem, or vertebral artery injuries have been suspected but never proven.^{47,48}

NATURAL HISTORY

Transition from Acute Whiplash Injury to Chronic Whiplash-Associated Disorder

Motor vehicle collision patients (10–40%) who suffer neck pain go on to develop chronic WAD.^{49–51} A systematic review and meta-analysis has suggested that substantial recovery occurs in most patients during the first 3 months following injury, and this initial period is characterized by a relatively rapid reduction in pain and disability.⁵² Although the pattern of recovery varied widely among patients, a trend was observed toward relatively little further improvement after 3 months. Across multiple clinical studies, the single strongest predictor of developing chronic WAD appears to be initial patient-reported pain level and disability.^{53,54}

Psychosocial Factors

It is generally accepted that psychosocial factors such as depression, coping skills, pain beliefs, and expectation for recovery play an important role in the variable expression of chronic pain in individual patients, especially in terms of how pain becomes disability. In some cases, such factors may amplify otherwise mild and tolerable pain into completely disabling pathology. It is also possible that these factors may prolong pain and disability from otherwise self-limited and recoverable injury.

Data from a population-based cohort study suggests that a patient's own expectation of recovery is a significant

independent predictor of clinical recovery from whiplash injury.⁵⁵ Based on these findings, a large prospective randomized controlled trial of 3,851 whiplash patients was performed in the United Kingdom to determine whether either specialized training of emergency department staff to provide active management consultation to whiplash patients or a course of physical therapy may yield superior outcomes compared to usual care.⁵⁶ The more active consultation was designed to enhance patient expectation of recovery by providing direct individualized education about the benign nature of their injury and the likelihood of rapid improvement through simple resumption of routine physical activity. Unfortunately, at 12 months follow-up, no significant difference in neck disability index score was observed between groups. More active counseling by emergency department staff yielded no discernible benefit, and although the physical therapy provided a modest benefit in terms of accelerated recovery, the difference was not found to be cost-effective and was not recommended.

It has been proposed that the transition from acute whiplash injury to chronic WAD may be mediated in part by maladaptive changes in central pain processing. According to this theory, a traumatic experience with or without accompanying tissue injury can trigger a hyperexcitable state within the central nervous system and lead to lasting impairment of endogenous pain mitigation. Neurophysiologic changes in the central nervous system have been observed in both the brain and spinal cord in association with chronic low back pain, fibromyalgia, and whiplash injury.^{57–59} This altered state can lead to affected patients experiencing pain with normally nonpainful stimuli, greater than expected pain with mildly painful stimuli, and significantly expanded pain distributions.⁶⁰

A popular biopsychosocial model for the development of chronic musculoskeletal pain is the fear-avoidance model. This theoretical model postulates that a subpopulation of patients with initial benign musculoskeletal pain following injury suffer excessive fear and anxiety that such pain signifies ongoing tissue injury and therefore go to great lengths to avoid physical activity and movements that may provoke pain. The result is a downward spiral of disuse-related weakness and deconditioning, persistent or worsening pain, disability, fear, and anxiety.⁶¹

The two central concepts of fear-avoidance behavior are catastrophizing and kinesiophobia. Catastrophizing refers to exaggerated negative interpretation of actual or anticipated pain.⁶² Although research has suggested that

level of catastrophizing is associated with current levels of disability in neck pain patients, the data with respect to prognostication is mixed.^{63,64} Kinesiophobia refers to pain-related fear of movement or activity. Again, the data with respect to prognostic value of observed kinesiophobia in terms of transition from acute whiplash to WAD is indeterminate.^{3,65} At this time, although the fear-avoidance model is widely believed to be a significant factor in the development of chronic low back pain and disability associated with both injury-associated and nontraumatic scenarios, there remains little clinical evidence that this is a determining factor in a majority of patients suffering from WAD.

Finally, 15–25% of WAD patients may suffer from some element of post-traumatic stress disorder (PTSD).⁶⁶ In patients who describe symptoms of repeatedly re-experiencing, the traumatic event cognitive behavioral therapy may be effective in reduction of the PTSD symptoms specifically.⁶⁷

Genetic Factors

It is widely recognized that the same type and severity of tissue injury in different individuals are associated with wide variation in reported pain levels. The propensity to develop chronic pain and symptomatology following injury is similarly variable. At least some of these population-wide variations appear to be due to genetic factors. Prevalent polymorphic variations of the catecholamine-O-methyltransferase gene (*COMT*) and guanosine triphosphate cyclohydrolase genes (*GCHI*) have been shown to affect persistent pain levels following spinal fusion surgery.^{68,69} A genetic study of patients presenting to the emergency department immediately following a motor vehicle accident revealed that patients with specific pain-sensitive forms of *COMT* were twice as likely to report moderate-to-severe neck pain and dizziness and three times as likely to report moderate-to-severe headache.⁷⁰ Of interest, compared to patients without the pain-sensitive forms of the gene, these patients also estimated that physical recovery would require on average twice as long.

Predictors of Outcome

The most recent natural history data suggest that by 1 year after whiplash injury as many as 50% of patients continue to be symptomatic.⁷¹ The Quebec Task Force on Whiplash-Associated Disorders generated a grading system that has performed poorly in terms of predicting chronic pain

and disability in individual patients. In the vast majority of published cohort studies, initial level of reported neck pain remains the single most predictive factor in terms of recovery with higher levels of pain portending poorer long-term prognosis.^{52–54} One prospective study suggested three different patterns of recovery over the first year.⁷² About 45% of patients reported initial mild levels of pain and disability, and demonstrated rapid and complete recovery. About 39% of patients reported initial moderate levels of pain and disability and demonstrated slower recovery to the point of persistent mild symptomatology at 1 year. About 16% of patients reported initial severe levels of pain and disability and continued to report chronic moderate-to-severe symptoms at 1-year follow-up. Another review combined results from eight different studies and identified a cutoff point for visual analog scale pain score of 5.5 out of 10 beyond which patients demonstrated over five times the risk of developing chronic pain or disability.⁷³

Although initial pain level is the strongest predictor of developing chronicity, variation in initial pain level accounted for only 15.7% of the variation in pain and disability observed at 1 year in one study.⁷⁴

Several studies have suggested that presence of associated symptoms such as headache, dizziness, upper extremity pain, numbness, or paresthesia may also be risk factors for chronicity, although correlations with these symptoms have been inconsistent.⁵³ Symptoms of insomnia and reported cognitive impairment have not been consistently associated with prognosis.

Among crash-related factors, not wearing a seatbelt appears associated with increased risk of chronic pain and disability.^{73,75} Among sociodemographic factors, female gender and lower levels of formal education have been frequently reported risk factors, while age appears to have little predictive value.⁷⁵ Pre-existing neck pain represents a small but significant risk factor.⁷³ In terms of physical findings, diminished neck range of motion may be a risk factor for chronicity with one study showing a nearly five-fold increased risk of disability at 1 year when decreased neck motion was measured on initial evaluation.^{3, 54,76} In multiple studies, patients who demonstrated lower levels of measured cold pain tolerance tended to experience poorer recovery.^{3,77} Findings with respect to various psychosocial factors have varied considerably across studies with generally weak evidence, suggesting that depression, poor coping skills, fear-avoidance behavior, and pain

catastrophizing may be associated with poorer outcome.⁷⁸ By contrast, patients who reported lower expectations for recovery were found to suffer higher degrees of chronic pain and disability, suggesting the possibility that a patient's own expectations may be an important prognostic variable.⁵⁵

Cultural factors may be a determinant of long-term disability perhaps due in part to influence on patient expectations. A so-called "whiplash culture" has been described in specific countries such as the United States, Canada, and the United Kingdom.⁷⁹ Overall rates of chronicity appear dramatically higher in these countries compared to inhabitants of Germany, Greece, and Lithuania.^{79,80} The Netherlands may also represent an environment that promotes chronicity following whiplash injury, with one report revealing 21.7% of patients continuing to be work disabled 1 year following injury.⁸¹

Although the issue remains controversial, some studies have suggested that legal representation as well as compensation through a tort-based insurance system may prolong recovery.^{18,82} The so-called "compensation hypothesis" proposes that compensation factors are directly or indirectly associated with worse outcomes following injury and that this relationship may account for more chronic and severe pain and disability that is observed even in the absence of observable tissue injury. This phenomenon has been attributed to insurance and medico-legal systems in which patients are expected to prove the extent of their poor health and functional disability in an adversarial setting and in which the amount of their compensation is directly tied to the severity of their condition. The hypothesis has been supported by studies reporting poorer outcomes associated with lawyer involvement and tort-based compensation systems.^{16,18,83-86} However, multiple investigators have vigorously challenged the validity of such conclusions on the basis of methodologic bias in the referenced studies, including the problem of reverse causality because that more severely injured patients are more likely to pursue compensation. As a result, it is reasonable to assume that the status of compensation is also the direct consequence of more severe injury.⁸⁷

MANAGEMENT

The initial evaluation of a patient presenting with neck pain following a whiplash-type injury mechanism should follow guidelines established and previously presented in this textbook regarding evaluation and management of cervical spine trauma. Initial history and physical examina-

tion should be directed toward determining the likelihood that a more serious and potentially unstable cervical spine injury has occurred. Appropriate plain radiographs and/or computed tomography (CT) should be obtained to rule out conditions such as spinal fracture or dislocation. It is critical for the lateral X-ray to include the cervicothoracic junction to avoid missing injuries in the lower cervical spine. In the setting of high set shoulders or incomplete imaging, it is imperative to obtain a CT scan. In the setting of neurological symptoms or deficits on examination, advanced imaging such as MRI or CT myelogram is required to rule out spinal cord or nerve root compression that may indicate the need for early surgical decompression. Ligament disruption resulting in potentially dangerous spinal instability may be apparent during initial evaluation, but acute muscle spasm may delay recognition of this type of injury until subsequent follow-up evaluation days to weeks later. Therefore, patients unable to provide adequate flexion-extension views on plain radiographs should be placed in a hard collar until their cervical spine can be clinically cleared. If a ligamentous injury is suspected, an MRI can be used to evaluate discoligamentous injuries.

When patients have been cleared of osteoligamentous injury, ongoing neck pain and stiffness are often provisionally diagnosed as cervical strain or acute whiplash injury. In the absence of a neurological deficit on examination, arm pain symptoms alone do not mandate initial evaluation with MRI. Appropriate evaluation of the upper extremity itself, however, may be required depending on the presence of additional findings on history or examination. Persistent pain on follow-up evaluations should prompt consideration of advanced imaging such as MRI, particularly if pain levels are not significantly improved by 6 weeks postinjury. The absence of more specific diagnostic findings such as cervical disc herniation, stenosis, or ligament injury supports an ongoing working diagnosis of cervical strain or acute whiplash injury.

Objective findings on physical examination are limited. Patients are generally found to be neurologically intact and any positive findings are typically nonspecific. The most common manifestations of whiplash injury and WAD are abnormal neck posture and motion, including restricted global patient-generated active range of motion and disordered patterns of movement.^{48,88} Specific characteristics include reduced acceleration and velocity of active neck movement, reduced smoothness, and irregular axes of movement.⁸⁹⁻⁹¹ These findings are most likely due to pain-related inhibition of normal movement as opposed to any readily identifiable structural disturbance.

Currently available clinical practice guidelines for the management of whiplash injury and WAD remain relatively vague. Typical recommendations focus on patient reassurance regarding the benign nature of whiplash injury and advice for continuing routine physical activity as tolerated.^{92,93} Nonspecific exercise is also commonly advised.⁹⁴

Despite an abundance of more active treatment options, there remain few with good clinical evidence supporting efficacy. Symptomatic use of nonsteroidal anti-inflammatory medication is reasonable as is use of local cold or heat therapy. Although these may provide temporary alleviation of pain, there is no evidence demonstrating that any medications or modalities foreshorten the overall period of pain or disability. If stronger narcotic pain medications or muscle relaxants are prescribed, it is recommended that these be provided for short-term relief of acute symptoms only.

Patient education appears to be an important component of efficient recovery. A prospective randomized trial comparing four weekly information sessions to usual care showed superior results among patients receiving more intensive personal education.⁹⁵ Even viewing an educational video appears to provide a modest degree of improved recovery over standard care.⁹⁶ Simply handing out educational pamphlets appears to provide no measurable benefit above standard care.⁹⁷

Physical therapy may be of benefit when utilized after the acute postinjury phase. A prospective randomized trial of treatment during the acute period compared a 6-week course of physical therapy to a 1-hour information session with a nurse and found no observable advantage from the physical therapy.⁹⁸ However, a randomized trial from Sweden demonstrated that physical therapy performed in more delayed fashion was associated with significant improvement in neck pain and headache at 6 months.⁹⁹ If some form of physical therapy is prescribed during the acute phase, neck mobilization may be the most beneficial prescribed treatment given that more rapid recovery has been observed with mobilization exercises compared to collar treatment and rest.^{100,101} Passive modalities such as diathermy, hydrotherapy, heat, and cold treatments have not been shown to be of clear benefit.^{79,102} Similarly, there is insufficient evidence to recommend other interventions in the acute phase, including pharmacologic agents, injection-based treatment, traction, or spinal manipulation.¹⁰² A Cochrane Review of nonoperative treatment for acute, subacute, and chronic WAD has concluded that there is insufficient evidence to support any specific exercise regimen.¹⁰³

While numerous studies have failed to demonstrate any benefit from medical intervention to treat acute whiplash injury, there is good data suggesting that excessive health care interactions during the acute postinjury phase may actually be detrimental in terms of speeding recovery. In one study, both options of a multidisciplinary outpatient rehabilitation program and directed fitness training within 120 days of injury were associated with slower recovery compared to usual care.¹⁰⁴ This trend was also observed in another Norwegian study of multidisciplinary care.¹⁰⁵

Medial Branch Blocks

Clinical evidence supports specific treatment of pain originating from the zygapophysial joints. Prior to treatment, cervical spine medial branch blocks are required as a diagnostic test for pain originating from these joints.¹⁰⁶ This approach involves anesthetizing median branch nerves that innervate a specific joint with a small volume of local anesthetic. Using this method, it has been estimated that as many as 50% of patients suffering chronic neck pain may have a component of pain originating from one or more joints.¹⁰⁷⁻¹¹⁰ However, it should be noted that this finding has also been observed in chronic neck pain populations regardless of whether a history of whiplash injury is present.¹¹⁰ The most commonly affected segments, based on response to such blocks, appear to be C5–C6, C2–C3, and C6–C7.²⁹ Although there is little evidence for the success of intra-articular facet injections, anecdotally facet injections can also be useful for whiplash-based pain.

Radiofrequency Neurotomy

If patients respond favorably to diagnostic medial branch blocks, radiofrequency neurotomy can be an effective treatment option. A randomized, controlled, double-blind trial enrolling 24 patients with neck pain following motor vehicle accidents demonstrated superior results in treated patients.¹⁰⁹ All patients in the study had presumed zygapophysial joint pain based on response to diagnostic blocks. The control patients received sham treatment in which the radiofrequency current was not turned on. The median time required for pain to return to 50% of pretreatment levels was 263 days in the study group versus 8 days in the control. In terms of complications, several patients reported prolonged numbness in the territory of the injected nerves, but none considered the localized sensory loss troublesome.

This treatment also appears effective for cervicogenic headache thought to arise from the third occipital nerve branch arising from the posterior division of the C3 nerve root of the C2–C3 segment.^{111,112} In terms of headache, neurotomy has been associated with pain relief lasting a median of nearly 300 days.

Following initial successful treatment results, pain typically recurs gradually over a year or so secondary to nerve regrowth. Repeat treatment generally re-establishes good pain relief but often for progressively shorter intervals.¹¹³

CONCLUSION

Current best evidence suggests that actual tissue damage is an important etiologic factor in generating pain and disability in WAD. The absence of observable tissue injury on advanced spinal imaging should not be interpreted as signifying the absence of true injury or WAD. Although the pattern of injury may be variable, lesions affecting the zygapophysial joints currently appear to be the most common identifiable and treatable injury. Once started, maintenance of WAD-related symptoms and disability may often depend at least in part on fear-avoidance behavior and psychobiological factors. There is currently no consensus regarding the role of litigation and/or workers' compensation on WAD natural history or disability. Inconsistent findings by different studies may be due in part to significant differences in litigation environment and workers' compensation systems in different regions and countries.

Regardless of the presence of psychosocial factors such as depression and anxiety disorders, legitimate injury remains the critical triggering and determining factor in most cases. Often, effective pain relief methods lead to parallel reduction of the psychological and behavioral manifestations of these other conditions.¹¹⁴

At this time, a patient-specific personalized approach to treatment is limited by the absence of strong predictive factors indicating patients at high risk of chronicity. From a practical standpoint, it is reasonable to simply provide education and reassurance regarding the generally benign nature of uncomplicated whiplash injury, encourage continuation of work and physical activity, and monitor symptomatology during the acute postinjury time period. Patients who fail to demonstrate expected levels of recovery after 2–3 months should be the target of more extensive evaluation and treatment.

Unfortunately, at this time there is no good clinical evidence that any proposed risk factor is modifiable to the extent of affecting natural history.

There is little data to support a role for surgical treatment other than in cases of clearly defined anatomic derangement such as cervical spine fracture, dislocation, or ligament disruption resulting in instability. Surgery is also appropriate in the setting of ongoing pain or neurological deficit associated with disc herniation or spinal stenosis. However, these conditions represent distinct diagnostic entities that should be excluded upon initial evaluation, and by definition, are not a component of simple whiplash injury. In select cases, surgery may be an option for patients with presumed discogenic pain emanating from one or two levels, although this remains highly controversial.

For patients with potential zygapophysial joint-related pain suggested by response to multiple diagnostic medial branch blocks, radiofrequency nerve ablation treatment is a reasonable option that has been associated with lasting pain relief. Surgical treatment in this population has not been formally evaluated or reported and cannot be recommended at this time.

METHODS OF CLOSED TREATMENT

Orthoses

Orthoses are externally applied devices that restrict motion, correct deformity, or improve function when a pathologic or iatrogenic process has impaired stability.¹ Spinal orthoses can be divided on the basis of the spinal segment they immobilize: cervical orthoses (CO; soft or hard collar), cervicothoracic (CTO; 4 post collar, SOMI or sterno-occipito-mandibular immobilizer, halo-thoracic vest), thoracolumbar (TLO or Jewitt hyperextension brace), thoracolumbosacral (TLSO clamshell, anterior spinal hyperextension brace) and lumbosacral (LSO).²

Noninvasive Orthoses

A soft collar provides comfort but limited immobilization. It is commonly used in whiplash injuries or muscle strains to minimally restrict motion and acts as a patient reminder to avoid excessive motion or strain. Hard collars (Fig. 51.1) are available in several forms including the Aspen collar (Aspen Medical Products, Irvine, CA, USA), the Miami J (Ossur Americas, Foothills Ranch, CA, USA), and the Philadelphia collar (Philadelphia Cervical Collar Co., Thorofare, NJ, USA). The common design in these orthoses is a firm seating superiorly between the occiput posteriorly and the mandible anteriorly, and the upper thorax

Fig. 51.1: Cervical hard collar.

inferiorly. Most collars also include an anterior opening for a tracheostomy. Hard collars are used to immobilize the middle cervical spine and are generally reasonably effective in immobilization of the spine in flexion and extension, more so than in lateral flexion and rotation.³ Although a number of choices are available, in vivo evidence suggests that most of these orthoses are equivalent in efficacy.⁴ Patient choice and comfort, as well as prescriber experience should be considered in choosing an appropriate device. Cervicothoracic orthoses, like the SOMI brace and

Fig. 51.2: Halothoracic vest.

the Minerva brace (United States Manufacturing Company, CA, USA) are particularly useful for immobilizing the lower cervical and upper thoracic spine. Typical cervical hard collars lack effectiveness across this level.⁴

Complications from the use of noninvasive collars are relatively rare but do occur when they are used inappropriately.^{2,5} Consultation with an experienced orthotist is essential in limiting these sometimes significant events. Skin breakdown over the suprascapular areas and bony prominences, such as the occiput, mandible and sternum, occur especially in polytrauma patients and those with altered consciousness or loss of sensation. Rash, muscle atrophy and psychological dependence have been reported with orthoses.⁵ Hard collars have been shown to cause a small but significant increase in intracranial pressure.⁶ This may be especially important in severe head injury patients and hard collars should be removed at the earliest opportunity once the cervical spine has been cleared of injury.

Halothoracic Vest

The halo vest is a CTO that allows the most rigid immobilization of the cervical spine amongst all braces (Fig. 51.2). It is most effective in the upper cervical spine and across the occipitocervical junction.⁷ Although it is invasive and cumbersome, it remains an effective and accepted method for managing a number of cervical injuries and postsurgical instability. Patient discomfort, social stigma, cosmetic concerns and pin site scar formation are universal issues with a halo-vest and need to be addressed carefully by the treating surgeon to ensure good compliance. In a recent

survivorship analysis, 74% patients completed the prescribed period of halo vest without early removal, and in 85% of cases, treatment with halo vest was successful without revision to surgical management.⁸

The halo consists of a ring, four upright connecting rods, and a vest. In current practice, the ring is made of light weight radiolucent composite graphite materials. The “ring” is actually 2/3rd of a ring which opens posteriorly to allow a patient to lie supine. It is attached to the skull typically with 4 stainless steel pins. The vest is also lightweight and made of thermoplastic material. A noninvasive halo (NIH) consisting of a halo mask has been proposed as an alternative to invasive halo based on skull pins. Although an attractive option, there is insufficient data to establish its equivalence to the traditional halo-vest.⁹ The halo ring can also be used as a traction device instead of Gardner-Well tongs. This technique has the advantage that the traction device can be easily converted to a halo vest for definitive management. Contraindications for the halo include cranial fractures, infection, severe soft tissue injury at the proposed pin sites, cachexia, severe deformity, morbid obesity, poor compliance and patients with mental health disturbance.³

Application of the halo ring and vest follows a series of steps.¹⁰ It is often applied in a supine patient in spinal immobilization precautions. The use of several assistants for positioning and turns is mandatory. The first step is to determine the appropriate ring size (about 2 cm distance between the skin and the ring) and vest size. Pin sites are then shaved and prepared with antiseptic solution. The ring is then temporarily held in place by 3 positioning pins with plastic caps. The skin and deep tissues over the pin sites, including the periosteum, are infiltrated with local anesthetic. In adults, two anterior pins and two posterior pins are positioned within the ring. The anterior pins are placed 1 cm superior to the orbital rim, over the lateral two thirds of the orbit, below the level of the largest circumference (equator) of the skull, and should be placed with the patient's eyes closed to avoid skin tension. Placement of the posterior pins is more variable. They are usually placed 1 cm above the helix of the ear, below the level of the equator. The ring should be clear of any contact with the ear. Pins should be placed as perpendicular to the skull as possible to avoid complications.¹¹ The pins are tightened diagonally in 2-inch-pound increments up to 8 in-lb torque.¹⁰ Finally, locking nuts are then applied to prevent the pins from backing out. The vest is then applied and fixed to the

ring according to the steps outlined by each manufacturer. Careful adjustment can be performed using the vest apparatus to apply angular, compression, or distraction forces to the cervical or cervicothoracic spine. All pins should be retightened at 24 to 48 hours after initial insertion. In children, it is recommended to use multiple pins at low insertion torque (2–5 in-lb) because of their thin and pliable skull.^{12,13} Custom made rings and vests are often required.

Minor complications are frequent with prolonged use of the halo vest. Pin loosening is reported to occur in up to 60% patients.¹⁴ In the absence of signs of either superficial or deep infection, pins should be carefully retightened to 8 in-lb. If no resistance is met during insertion, a new pin at another location should be placed. Pin site infections occur in up to 13%.⁸ Initial treatment is local wound care and oral antibiotics. If conservative treatment fails to resolve the problem, the pin should be removed and replaced at a new site.¹⁰ Pressure sores from the vest and straps have been reported in up to 10% of patients.¹⁵ The physical limitations of the orthotic include swallowing difficulty and deglutition dysfunction, which can result in aspiration, especially in the elderly.¹⁶ Restriction of pulmonary function, pneumonia and thromboembolism have also been reported.^{14,17}

Other local complications include injuries to the supraorbital nerve, supratrochlear nerve, greater occipital nerve and zygomaticotemporal nerve from incorrect pin placement. Frontal sinus violation and skull fractures may occur from incorrect placement. Anterior pins that are placed too far laterally may cause inner table and dural penetration. The pin needs to be replaced and the dural tear usually heals with 4–5 days of conservative care including elevation of the head of the patient's bed.¹⁴ Although extremely rare, epidural abscess or meningitis may occur from inner table violation.

Halo vest use in elderly has significant morbidity and mortality^{18–20} in most studies, although evidence suggests that the reported high incidence of respiratory complications may have been overestimated.¹⁷ In either case, the use of invasive immobilization may impair mobility and be met with minor complications that have a more profound effect on those patients with a marginal medical status. As discussed later in this chapter, the use of an invasive orthotic in this group of patients should be measured against the lower risk of other devices, even if they are somewhat less effective at controlling motion or stability.

'Snaking' or paradoxical motion has been defined as movement in opposing directions at adjacent levels,

especially where the extremes of the spinal region are rigidly fixed.²¹ It has been shown to occur with all braces, including in the halo-vest. The significance of this issue lies in diminishing the immobilizing capacity of cervical braces and the halo vest especially from occiput to C2, and in the middle of the subaxial spine.²¹ Inadequately fitting braces and vests have been shown to increase 'snaking'.^{21,22}

CERVICAL TRACTION AND REDUCTION METHODS

Traction

Skeletal traction has been used for decades to reduce and sometimes definitively treat injuries of the cervical spine. A number of different methods are available, generally using an invasive device to attach to the skull combined with a system of weights. Countertraction is generally accomplished with body weight alone, but countertraction devices have also been employed.²³ Traction techniques may be used to treat malalignment and dislocations at any level of the cervical spine, although the specific methods involved and the chances of success vary in the lower cervical spine compared to the upper region.²⁴ Traction is most commonly described for flexion-distraction injuries (facet subluxations or dislocations), as well as cervical burst fractures, odontoid fractures, and spondylolisthesis of the axis.^{24–31} Contraindications to using traction include any distraction type injury (such as occipitocervical dislocation or Type IIA spondylolisthesis of the axis), as well as skull trauma that precludes the use of an invasive clamp.^{31–33}

Cervical traction requires a cooperative patient who may be examined before, during and after any manipulation. In practical terms, the setting is also critical. In many hospitals, the close monitoring of patients requires advanced physician and nursing care which is typically available on high observation wards or emergency rooms. All equipment should be prepared and immediately available, including radiology equipment for radiographic follow-up. It is also critical to plan for an unexpected neurologic deterioration. As described later in this chapter, a number of case reports have described sudden and catastrophic neurologic injury during cervical dislocation reduction.³⁴ If any neurologic deterioration should occur, traction should be stabilized or removed, radiographs should be obtained immediately, and other prompt investigations should be pursued to determine if a new compressive pathology has been created.

Figs. 51.3A and B: Gardner-Wells traction. (A) Positioning and application of tongs in posterior location to reduce a facet dislocation. (B) Inline traction using a rope and pulley system.

Various devices may be used to capture and control the skull. The most popular choices include a halo ring and Gardner-Wells tongs.^{35,36} Tongs may be applied quickly, even by those inexperienced with the technique, although the overall pull-out strength of the device is lower than a halo ring.³⁶ With the patient appropriately positioned, the scalp is prepared with antiseptic solution and local anesthetic is infiltrated in to the skin. For Gardner-Wells tongs, pins are usually inserted 2–3 centimeters above the pinna of the ear, and 1–2 centimeters posterior to the external auditory canal (Fig. 51.3A). This position avoids damage to other structures such as the superior temporal artery. The pins are symmetrically advanced until a piston within the pins pushes outwards to become flush with the pin head. The posterior position allows for slight flexion of the neck, which assists in the reduction of dislocations and other flexion or compression injuries.²⁸

Sequential weights are then applied to the ring via a rope and pulley system (Fig. 51.3B). It is critical to provide adequate analgesia for the patient to maintain their comfort and cooperation. Narcotic analgesics, muscle relaxation, and mild sedatives are all useful adjuncts. The time required and amount of weight varies in different published descriptions of the technique.^{24,28,29,37} Typically, between 5 and 10 kg is used to begin, which roughly offsets the weight of the head. A small period of time is allowed to ensure that the patient is comfortable and to permit any stretch or creep. Different authors describe waiting from 2 to 30 minutes per step, although the decision regarding rapidity of the reduction should be assessed depending on the clinical situation and patient factors.^{24,28,37} Weight

is then added in 5 kg increments.²⁴ The total amount of weight allowable can vary up to approximately 55 kg or 80% of the patient's body weight.^{28,29} Higher amounts of weight are generally required for fractures lower in the cervical spine, as well as for bilateral and nonfractured injuries (i.e. pure facet dislocation). For each level away from the skull, an additional 5–10 kg may be required beyond the initial 10 kg.^{28,38} It is critical to perform both clinical and radiographic assessments frequently during reduction. Mobile X-ray equipment is a helpful adjunct if traction is applied on a routine hospital ward. In some cases, gentle manipulation or adjustments may be required. Flexion of the neck by altering the trajectory of the weight and counterweight often assists in reducing flexion distraction injuries such as facet dislocations.³⁸ In the case of a unilateral injury, lateral rotation towards the injured side may force the dislocated inferior articular process to clear the superior facet below and reduce into anatomic alignment. These manipulation maneuvers must be done carefully in a relaxed patient to avoid complex motions that may increase the risk of neurologic injury such as nerve root palsy or cord injury.³⁷ If reduction is obtained and confirmed radiographically, traction and flexion are reduced or removed and a decision is then made with regards to definitive treatment. In the case of halo ring traction, a vest may be applied as either temporary stabilization until an operative procedure, or may be used as definitive treatment in some cases.^{39–41}

Several complications may occur from cervical traction in addition to those caused by the skull clamp itself. These include 6th cranial nerve palsy, osteomyelitis,

pressure sores, scalp hemorrhage, and failure of the clamp.^{42,43} These are generally avoided with proper technique and good nursing care.

INJURIES OF THE UPPER CERVICAL SPINE

Occipitocervical Dislocation

Occipitocervical dislocations are high energy injuries and are usually fatal, but more survivors are being reported because of improvement in on-scene emergency management as well as diagnosis and definitive management.³² These injuries are also found more commonly in pediatric cervical spine trauma than previously thought.³²

Traction is contraindicated in these injuries and the initial management is with halo-vest immobilization.³² Radiographic parameters to diagnose this injury include the Power's ratio and the Harris lines (basion-dens interval and basion axial interval). Criteria for diagnosis include.^{44,45}

- Power's ratio > 1,
- Basion-dens interval > 12 mm,
- Basion axial interval > 12 mm or < 2 mm
- Widening of the O-C1 joint.

In equivocal cases, an MRI may provide valuable information regarding the integrity of the anterior and posterior atlantooccipital membrane, tectorial membrane, apical, alar and cruciate ligaments (the craniocervical stabilizers) in these difficult injuries. These injuries are considered highly unstable and surgical occipitocervical fixation is recommended. With advanced imaging modalities, however, a new subgroup of patients with normal parameters on X-ray and CT but signal change on MRI in the posterior ligaments or occipitoatlantal joints have emerged.^{46,47} This subgroup can be managed with collar or halo-vest, unless there is unequivocal evidence of complete disruption of the craniocervical stabilizers on MRI. Due to potential for catastrophic neurological injury, extremely close follow-up with radiographs is mandatory.

Occipital Condyle Fractures

Occipital condyle fractures are becoming recognized more frequently in recent years as a result of advances in imaging and patient survival.⁴⁸ These fractures may be a part of disruption of the atlanto-occipital complex.⁴⁸ They are most frequently the result of high velocity injuries, especially motor vehicle collisions. Anderson and Montesano

classified these fractures into 3 types.⁴⁹ Type 1 injuries are comminuted, impaction fractures, Type 2 fractures extend into the skull base and Type 3 injuries are alar ligament avulsion fractures. Type 3 is the most common and Type 1 is the rarest. Traditionally, Type 1 and 2 fractures were considered stable and treated nonoperatively, whereas Type 3 fractures were considered unstable and occipitocervical fusion was recommended.

Recently, this guidelines has been refuted. It has been proposed that it is the only the presence of associated occipitocervical instability that dictates the need for surgical fixation.^{50,51} Subsequently, it has been confirmed that even Type 3 injuries and bilateral fractures can be managed nonoperatively if there is no evidence of occipitocervical instability or associated cervical fractures.^{48,52} Use of a hard cervical collar for 6 weeks is usually adequate and a halo-vest is usually not necessary for management of these injuries.^{48,52}

C1 Fractures

The most common C1 fracture requiring treatment is a vertical compression or burst fracture (Jefferson fracture). The stability of these injuries is judged based upon the integrity of the transverse ligament.^{53,54} If the sum of the C1 lateral masses overhang (measured on an open mouth view or a coronal CT) with respect to the C2 lateral mass is greater than 7 mm, the transverse ligament is considered disrupted (rule of Spence).⁵⁵ Alternatively, MRI is highly sensitive for diagnosing transverse ligament disruption. Regardless of the diagnostic method, complete disruption of the transverse ligament is a contraindication for closed treatment. Fractures with no evidence of transverse ligament disruption as well as avulsion fractures of the transverse ligament are amenable to healing with external immobilization, in a hard collar or halo-vest for 8–12 weeks.⁵³ Closed management can also be used to minimize surgical treatment even when transverse ligament disruption is present. Initial management of an unstable C1 fracture in a halo-vest typically results in healing of the bony injuries, resulting in isolated atlantoaxial instability. Subsequent surgery involves only C1–C2 arthrodesis, thus occipitocervical fusion can be avoided. Finally, atlas fractures are frequently associated with odontoid or other C2 fractures. These fractures generally involve only the posterior arch. In these circumstances, the associated injuries dictate the management unless the atlas fracture by itself is unstable.^{53,54}

Figs. 51.4A and B: Type II odontoid fracture with minimal anterior displacement and reverse obliquity pattern ideal for closed treatment in a halothoracic vest or similar device.

Odontoid Fractures

Odontoid fractures are the most common C2 fracture. Anderson and D'Alonzo classified odontoid fractures into 3 types.⁵⁶ Type 1 fractures represent an avulsion fracture of the alar ligament and appear as an oblique fracture through the tip of odontoid. Type 2 fractures are the most common and occur at the junction of the dens with the C2 body. Type 3 fractures extend into the cancellous portion of the axis body. Treatment options include hard cervical collar, halo-vest, anterior odontoid screw fixation or posterior C1–2 arthrodesis. Treatment is based on fracture type, patient age, displacement (> 5 mm), angulation ($> 10^\circ$), comminution and integrity of the transverse ligament. Transverse ligament disruption necessitates C1–C2 arthrodesis.

Type 1 fractures are considered stable and can be managed with a hard cervical collar for 6 weeks. Occipito-cervical dislocation should be ruled out as at least one of the alar ligaments is always injured. Undisplaced type 3 fractures have a high potential for union (given their location in cancellous bone) and should be immobilized in a halo-vest or a hard cervical collar for 12 weeks.⁵⁷

Type 2 fractures have a high potential for nonunion (because of their location in a hypovascular watershed area) and have attracted a great deal of controversy regarding their management. In the elderly, nondisplaced type 2 fractures (typically caused by low energy injuries) can be managed with a hard cervical collar for 12 weeks.^{58–61} Even though nonunion rates with this method may be very high (especially in the elderly), a stable asymptomatic fibrous

union is usually achieved.^{18,60} In this population, even movement at the pseudoarthrosis does not often lead to an adverse clinical outcome.⁶¹ Halo-vest application in elderly is poorly tolerated and has been shown to be associated with significantly increased morbidity and mortality.^{18–20}

Nondisplaced type 2 fractures in a young patient may be treated with immobilization in a halo-vest or hard cervical collar for 12 weeks.⁶² Comminuted and reverse obliquity pattern fractures are also generally treated with a halo-vest, as anterior fixation is generally not feasible and posterior fusion carries significant morbidity in loss of motion (Figs. 51.4A and B). Displaced or angulated fractures may be reduced with halo traction, followed by immobilization in a halo-vest. Frequent radiological follow-up is necessary as the reduction can be unstable and transition to surgical management may be required. The nonunion rates for displaced type 2 fractures are higher when external immobilization is used, but the advantages of preserving motion at C1–C2 are obvious.²⁶

C1–C2 Subluxation

Rotatory subluxations of C1 on C2 are high energy injuries in adults, but can occur more frequently in children. Fielding and Hawkins classified rotatory C1–C2 subluxation into 4 types.⁶³ Type 1 has no anterior displacement, Type 2 has anterior displacement less than 5 mm (mild transverse ligament deficiency), Type 3 has anterior displacement > 5 mm (transverse ligament is ruptured) and Type 4 is a posterior dislocation.

Figs. 51.5A and B: Type II Hangman's fracture treated with external stabilization in a halo-thoracic vest.

Type 1 and 2 injuries are differentiated from more severe forms because the transverse ligament remains intact.⁶³ As a result, these can be treated with closed reduction (with transoral digital manipulation if needed) with a halo ring and traction and can be converted to a halo-vest or even a hard cervical collar for definitive management for 10–12 weeks. Irreducible dislocations as well as more severe injuries are not amenable to closed treatment.

Other C2 Fractures

Unilateral or bilateral fractures of the C2 lamina, articular facets, pars or pedicle are usually included in traumatic spondylolisthesis of axis (Hangman's fracture). This injury pattern is essentially an injury to the C2–C3 motion segment. Effendi et al. classified these injuries into 3 types.⁶⁴ Type 1 has < 3 mm displacement and no angulation (C2–C3 disc, anterior longitudinal ligament (ALL), posterior longitudinal ligament (PLL) are intact), Type 2 has > 3 mm displacement and some angulation (C2–C3 disc, ALL or PLL are injured) and in Type 3, the C2–C3 facet joints are dislocated. These injuries are usually hyperextension injuries, but Levine and Edwards described a Type 2A flexion-distraction injury, associated with acute angulation in flexion, but no displacement, of C2 with respect to C3.³³ These fractures are markedly unstable in distraction, so it is critical to recognize this pattern and differentiate it from other Type 2 injuries which can often be reduced by closed methods.

Generally, Type 1 fractures are managed with halo-vest or hard cervical collar immobilization for 6–8 weeks.²⁵ Most Type 2 fractures can be managed with a halo-vest

or hard cervical collar for 8–12 weeks with spontaneous fusion across C2–3 disc in many cases²⁵ (Figs. 51.5A and B). Displaced Type 2 fractures can be reduced in halo traction followed by conversion to halo-vest for definitive management.^{27,65} Most Type 2A and Type 3 fractures are not amenable to closed treatment beyond reduction and require open stabilization.^{25,27,65}

SUBAXIAL CERVICAL SPINE FRACTURES

Assessing Stability for Closed Treatment

Traumatic fractures of the subaxial cervical spine range from very stable, benign injuries to frank clinical instability resulting in early neurologic injury. A number of anatomic and mechanistic classifications identify characteristics of the unstable spine, which also characterizes the appropriateness of closed treatment.^{66–68} The Subaxial Cervical Spine Injury Classification System (SLIC) includes three domains (morphology, neurologic status, and discoligamentous complex injury) and assigns a score on which surgical stabilization may be justified.⁶⁷ More traditional approaches infer instability from radiographic criteria,⁶⁸ and it has been suggested that these criteria may also be used to justify surgical stabilization over closed management.⁶⁹ In either case, it is important to recognize that despite a great deal of clinical experience and biomechanical evaluation, little consensus exists among experts regarding optimal management of many subaxial

cervical injuries,^{38,70,71} and a clear understanding of the principles and limitations of closed cervical management is required.

Cervical Spine Dislocation/Subluxation

Reduction

Subaxial cervical dislocations may be both reduced and potentially stabilized by closed methods. Historically, some authors had advocated stabilization in situ for dislocated facets, but due to poor outcomes, this technique has been abandoned.³⁰ Reduction is considered mandatory to both restore alignment and if necessary, decompress the neural elements. The use of closed traction or manual reduction to restore alignment remains controversial, largely due to a series of case reports describing iatrogenic neurologic injury.^{34,37} It has traditionally been felt that these neurologic injuries are the result of displacement of large disc or endplate fragments in to the spinal canal during the reduction.³⁴ Complex, difficult, or delayed reductions are thought to increase this risk.³⁷ In order to assess the risk of this complication, many authors have stressed the importance of obtaining an emergent MRI prior to closed reduction to rule out any substantial disc material behind the superior vertebral body of the dislocated level.^{34,38} Experts continue to vary, however, in both their use and interpretation of MRI,⁷⁰ and more recent imaging studies have failed to support the claim that disc material commonly herniates in to the canal.⁷² Despite the controversy, the use of closed reduction techniques as described earlier in this chapter and by other authors^{28,29} remains a viable and popular step in the management of cervical dislocations with or without fracture, but must be used with caution. In certain circumstances, MRI is required:

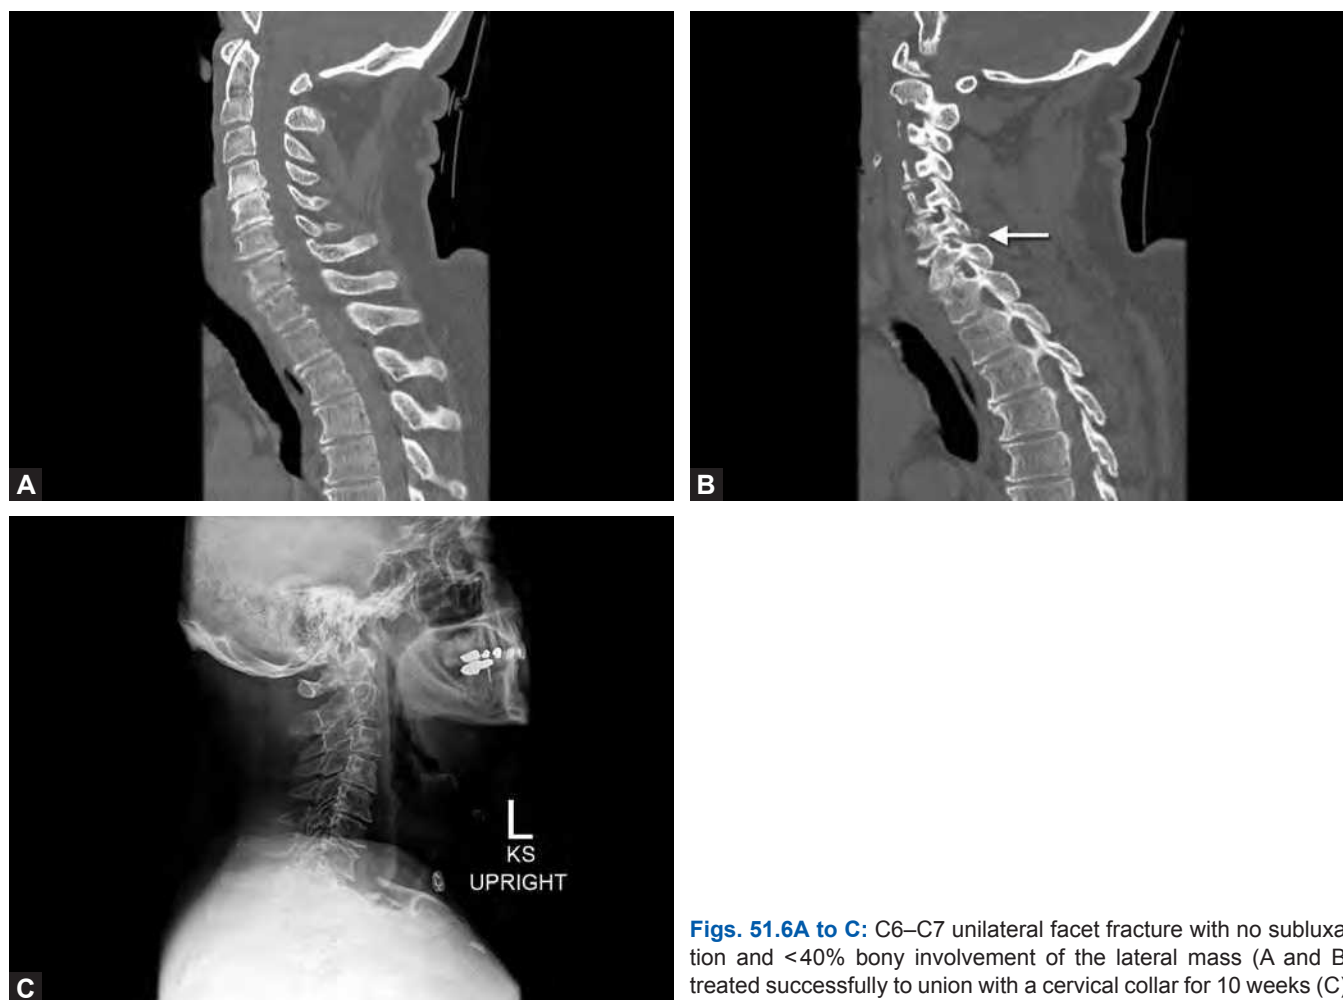

- Obtunded or unexaminable patients either with or without neurologic injury
- Dislocations in which posterior-only surgery is planned with reduction under anesthetic.

In other settings, closed reduction may be performed either in the awake patient or anesthetized patient at the discretion of the consultant after review of the available imaging. Close neurologic monitoring or immediate surgical decompression and stabilization is mandatory, regardless of the treatment algorithm used and the availability of MRI.

Stabilization and Definitive Treatment

The use of cervical orthoses for both subluxed and dislocated facet fractures as well as undisplaced injuries also remains controversial. Historically, closed immobilization has been used for subaxial fractures or dislocations following reduction even with neural element injury.^{29,30,73} In current practice, these injuries are nearly always treated surgically with both internal fixation as well as decompression of the neural elements. In cases without neural element injury, several studies have assessed radiographic predictors of stability using both CT as well as MRI scanning. It is presumed that injuries without hallmarks of instability on initial imaging are less likely to progress to healing in an unfavorable position and are also less likely to deform over time, potentially creating secondary neurologic injury and neck pain.^{41,74,75}

In general terms, in patients with more substantial bony injury, even if there is no initial malalignment of the spinal column, instability is considered more likely. For example, the linear extent of the fracture in an initially undisplaced injury has been shown to be predictive of late instability, particularly if the fracture involves greater than 40% of the lateral mass.⁷⁶ This measurement can easily be assessed on imaging that is universally obtained in patients with a cervical injury. Fractures involving both the superior articular process of the inferior vertebra and the inferior articular process of the superior vertebra (i.e. a “kissing” fracture) are also inherently less stable and are not appropriate for closed treatment.⁷⁷ Fractures involving a “floating” joint with fractures of both the lateral mass and pedicle also respond poorly to closed treatment resulting in a high incidence of ongoing radiculopathy.⁷⁸ Several studies have also demonstrated increased instability and higher failure rates with closed treatment for lateral mass fractures that are associated with vertebral body compression or burst fractures, and those associated with initial kyphosis on initial radiographs.^{41,75,77,79} In addition to plain X-ray and CT scans, MRI may be used to assess ligamentous disruption of the major stabilizers including the anterior and posterior longitudinal ligaments, the ligamentum flavum, facet capsules and interspinous ligaments. Disruption of three or more these structures has been found to be predictive of late subluxation in initially well-aligned fractures.⁸⁰ This latter finding is supported by expert opinion in the SLIC system.⁶⁷ Perhaps more intuitively, those injuries with initial subluxation or facet malalignment (perched or

Figs. 51.6A to C: C6–C7 unilateral facet fracture with no subluxation and <40% bony involvement of the lateral mass (A and B) treated successfully to union with a cervical collar for 10 weeks (C).

locked, especially bilaterally) are also less likely to remain in a stable position with the use of closed techniques alone.^{39,41,74}

Historically, closed treatment using a halo-thoracic vest was met with mixed results, largely because of the inclusion of patients with radiographic signs of more severe instability. Stable healing was the result in between 17–70% with most reports including some residual neck pain or symptomatic stiffness.^{39,41,73–75,79,81,82} Increased kyphosis or displacement was associated with increased pain or disability.^{73,75,82} More recent work has demonstrated acceptable outcomes in patients with unilateral fractures treated in halo-vest compared to early surgery, albeit with slightly worse outcomes in terms of bodily pain on standardized quality-of-life outcomes.⁸¹

Despite these limitations, however, closed treatment of particular unilateral facet fractures remains a viable

option for certain fractures without the worrisome radiographic parameters discussed previously (Figs. 51.6A to C). As discussed earlier in this chapter, either halo-vest or hard collar immobilization are reasonable choices, both offering relative advantages and disadvantages. Due to its invasive nature, the use of the halo-vest may carry additional risks including pin site infection and skin breakdown. In addition, it can have relatively poor control of some mid-subaxial injuries in control of flexion and extension due to the snaking phenomenon.⁷ Cervical hard collars are easier to apply and maintain, but lack the overall control of axial compression and overall neck motion afforded by a more rigid construct.⁴ Regardless of the method of immobilization, close follow-up is required. Numerous studies have outlined successful treatment with surgery during the first 2–4 weeks after injury if closed reduction fails to maintain alignment.^{29,30,77,79,82} Routine radiographs and clinical

examinations should be performed at least once during the first 2–3 weeks after injury to ensure that alignment is maintained and neurologic function is preserved. If closed treatment fails, open reduction after this time may become progressively more difficult and neurologic recovery (if a deficit exists) is less likely.²⁹ Duration of immobilization is generally 10–12 weeks, although considerable variation exists in the literature.^{29,30,39,41,77,79,81,82}

CERVICAL BURST AND FLEXION TEARDROP FRACTURES

The cervical spine is a relatively rare location for burst fractures, relative to the lower thoracic and upper lumbar spine.⁸³ The SLIC system defines a separate category in the morphology subcomponent for burst fractures, and these injuries are also outlined in the Allen classification, generally as vertical compression injuries.^{66,67} Flexion “teardrop” fractures are generally thought to represent a related flexion-compression mechanism with injury to the facet or posterior soft tissues, but without distraction of the posterior elements.⁶⁶

In terms of treatment, these injury patterns are often grouped together. In older studies, halothoracic vest treatment was met with a very high failure rate for maintenance of reduction as well as patient outcomes.^{29,39,41,74} Unfortunately, these older studies included a mix of fracture types that are sometimes not well described. More recent literature comparing surgical and closed treatment, however, also favors surgery in most cases. Halo traction followed by treatment in the halothoracic vest for 12–14 weeks is effective for preventing neurologic deterioration in most cases, but results in higher degrees of kyphosis.^{40,84} No difference, however, has been shown in patient-centered outcomes despite this radiographic difference.

In certain fracture types, however, closed treatment is a reasonable option, particularly where little chance of post-traumatic kyphosis exists. This situation is rarely the case when flexion-distraction or “teardrop” fractures are present; however, in the SLIC system, a burst fracture, even with complete disruption of the discoligamentous complex, does not score highly enough to justify routine surgical intervention unless there is subsequent neurologic compromise. If possible, closed treatment avoids the sometimes morbid stabilization and fusion of two intervertebral levels with a corpectomy or multi-level posterior stabilization. Pure burst fractures with intact posterior elements may be managed using a hard collar or halothoracic vest, depending on the degree of comminution and

Figs. 51.7A to C: C7 burst fracture with no significant kyphosis on computed tomography (A and B) and minimal posterior ligamentous disruption on magnetic resonance imaging scan (C). This pattern is ideal for closed treatment in either a hard-collar or halothoracic vest for 10–12 weeks.

other patient characteristics (Figs. 51.7A to C). Close radiographic follow-up is required to ensure that alignment is maintained and neurologic symptoms do not develop.^{40,41}

Figs. 51.8A and B: C2 extension teardrop fracture (A) treated to union (B) in a hard collar for 10 weeks.

Cervical Extension or Extension Teardrop Fractures

Unlike vertical compression or flexion-distraction injuries, extension injuries tend to be more stable and are more amenable to closed treatment. The determination of the mechanism of fracture can be difficult, and is based on the clinical history, associated injuries (such as scalp or facial trauma), and imaging. In the absence of ankylosing conditions, most extension injuries such as the C2 teardrop fracture may be adequately immobilized with a cervical hard collar for 8–12 weeks and union is generally expected (Figs. 51.8A and B). Neurologic complications are rare, and although limited literature is available on these injuries, available reports describe little, if any, late complications such as instability, pain, or functional impairment.^{85,86}

Spinous Process Avulsion (Clay-Shoveller's Fracture)

Fractures of the spinous process of the lower cervical (and upper thoracic) spine are colloquially known as Clay-Shoveller's fractures, after their description in a working population in western Australia.⁸⁷ These fractures are related to muscular avulsions of the spinous process and do not affect the overall stability or function of the spinal column. Kyphosis is rarely seen⁸⁷ even in neglected cases. Closed management is recommended, and the use of a hard or soft collar may help to limit pain during the early phase of recovery.

KEY POINTS

- Hard collars as well as invasive and noninvasive cervicothoracic orthoses each have relative benefits and drawbacks for immobilization of the cervical spine after injury. Treating physicians should be aware of the potential for complications from any orthotic.
- Cervical traction is a useful tool for reduction of many injuries including facet dislocations as well as upper cervical injuries. It should be avoided in patients with distraction type injuries.
- Upper cervical injuries should be carefully assessed for signs of relative stability before choosing closed management. Ligamentous as well as bony stability needs to be considered.
- Closed traction for subaxial cervical spine injuries is generally safe and effective, but in rare cases can be complicated by serious neurologic sequelae. There is no consensus algorithm for safe traction, but strong consideration should be given to emergent MR imaging before reduction.
- Definitive management of subaxial cervical injuries such as facet fractures and vertical compression fractures is often effective where relative stability is expected and there is little chance of progressive subluxation or angular deformity.

Cervical Spine Injuries in the Athlete: Return-to-Play Criteria

Venu M Nemani, Han Jo Kim, K Daniel Riew

Snapshot

- » Epidemiology
- » Anatomy/Mechanisms of Injury

- » Return-to-Play Criteria

INTRODUCTION

There are approximately 12,500 new cases of spinal cord injury (SCI) per year, with 8.4% of the total causes of SCI from sports injuries (compared with 39.1% from motor vehicle collisions).¹ While SCI is not as common as extremity injuries among athletes, these injuries are concerning because of the tremendous potential for morbidity and mortality. There is a large spectrum of cervical spine injuries, ranging from injuries that are largely clinically insignificant with no neurologic sequelae to devastating injuries that render the cervical spine unstable and cause dense quadriparesis. The difficulty and controversy arises when making decisions as to when an athlete can return to play (RTP) after a cervical spine injury. Medicolegal issues must also be considered, since the surgeon is making a recommendation that could result in catastrophic injury to the athlete who is prematurely or inappropriately returned to play. Unfortunately, no definitive guidelines exist due to the lack of high-quality evidence. Here, we present our expert opinion, supported by evidence when available, on RTP criteria for common injuries to the cervical spine sustained during sport.

EPIDEMIOLOGY

Since 2010, sporting injuries were the fourth most common cause of SCI in the United States after motor vehicle collisions, falls, and acts of violence.¹ Injuries to the cervical spine occur most frequently in athletes participating in

contact sports, and in the United States, particularly during American Football.^{2,3} Other sports that place athletes at high risk include ice hockey,⁴ wrestling,⁵ and rugby⁶; however, other sports during which SCI has been described include mountain biking,⁷ skiing or snowboarding,⁸ diving,⁹ and horseback riding.¹⁰ Certain injuries occur with alarming frequency such as burners/stingers, with 50% or more of college American football players reporting experiencing this injury.^{11,12} Other injuries are more rare but can have more dire consequences.

ANATOMY/MECHANISMS OF INJURY

Stingers/Burners

Stingers or burners are injuries that are characterized by weakness, paresthesias, and radiating pain that involves only a single extremity. The athlete typically complains of burning or tingling in an arm that is associated with weakness after an acute injury. Most episodes are transient, lasting from seconds to minutes; however, occasionally symptoms can be persistent for days to weeks. Symptoms classically are in a dermatomal or myotomal distribution if the injury is due to nerve root compression, although multiple levels are often involved with an injury to the plexus, which can cause a more confusing clinical picture. C5 and C6 are the most commonly involved levels, with resultant weakness in shoulder abduction (deltoid) and elbow flexion and forearm supination (biceps). There are multiple mechanisms that can cause a burner or stinger.

1. Traction injury to the brachial plexus that occurs with ipsilateral shoulder depression with side bending of the neck to the contralateral side.
2. Compression injury to a cervical nerve root that can occur with neck extension and contralateral rotation, or ipsilateral side bending.
3. Direct compression of the plexus at Erb's point, which typically occurs during American Football when the plexus gets compressed between the shoulder pads and the superior-medial scapula.¹³

Transient Quadripareisis

Transient quadripareisis is an injury characterized by paresthesias or weakness in more than one extremity, which is in contrast to a stinger or burner that only involves a single extremity. Torg et al.¹⁴ reported the incidence in college football players to be approximately 1.3 in 10,000 athletes. Symptoms can range from only mild paresthesias to a dense quadripareisis. The duration of symptoms is usually brief lasting only 10–15 minutes, but athletes can have residual symptoms lasting up to 36 hours. The mechanism of injury, as opposed to a burner or stinger, is typically forced neck hyperextension, causing spinal cord compression between the inferior aspect of the cephalad vertebral body and the superior edge of the lamina of the caudad level. Hyperflexion can similarly also result in cord compression. Patients with underlying cervical canal stenosis, either congenital or acquired, are thought to be at higher risk and have more frequent recurrences of transient quadripareisis.¹⁵ Other athletes at risk include those with any structural abnormalities of the cervical spine, including cervical kyphosis, Klippel-Feil abnormalities, cervical instability, and/or intervertebral disc protrusion or herniation.

Cervical Fractures

Cervical spine fractures represent a heterogeneous population of injuries, which can range from those that are essentially clinically insignificant (spinous process avulsion fractures) to those that can cause catastrophic neurological deficits (fracture/dislocations). Each injury must be evaluated on an individual basis as each has a unique mechanism and must be treated with the patient's underlying anatomy and sport-specific needs in mind.

Spinous Process Fractures

Spinous process fractures usually occur as a result of a strong contraction of the trapezius or rhomboid musculature, or a hyperflexion mechanism, causing an avulsion

fracture of the posterior elements. Less commonly fractures can result from a direct blow to the spinous process.

Compression Fractures and Burst Fractures

Compression and burst fractures occur from an axial load on the head with the neck in variable degrees of flexion. Compression fractures generally occur in lower energy mechanisms although this is not the rule. The major differentiating factor between burst fractures and compression fractures is that the posterior cortex of the vertebral body is disrupted in burst fractures, thus placing the cord at risk due to possible retropulsion of bony fragments.

Flexion-Distract Injuries

Flexion-distract mechanisms of injury can significantly destabilize the spine with resultant SCI and neurological deficit. These injuries occur with forced cervical flexion after axial loading of an already flexed neck. This results in an injury pattern with tensile failure of the posterior elements and subsequent fracture of the vertebral body, often with the production of a "teardrop fragment" involving the antero-inferior vertebral body. Although less common, facet dislocation without a concomitant articular process fracture can result in significant neural compression and injury as the intact articular processes act as a block to spontaneous reduction and subsequent canal decompression.

"Spear Tackler's Spine"

Spear tackler's spine represents a constellation of findings that includes vertebral body anomalies consistent with previous trauma, canal stenosis, reversal of the normal cervical lordosis, and a confirmed history of tackling while leading with the head ("spearing").¹⁶ These elements have been associated with a very high risk for neurological injury.

Stenosis

Congenital or acquired spinal stenosis involving the cervical spine can place athletes at higher risk for neurological injury due to decreased space available for the spinal cord. There have been various radiographic methods described for the detection and quantification of stenosis. One of the more frequently used methods described by Pavlov et al.¹⁷ is the Torg ratio, which compares the width of the vertebral body with the width of the spinal canal on a lateral cervical radiograph, with a ratio of <0.8 being used to

define cervical stenosis. Torg et al.¹⁸ examined American football players from high school to professional level that had suffered an episode of transient neuropraxia to determine whether there was any relationship to stenosis and found that a Torg ratio cutoff of 0.8 had high sensitivity (93%) for transient neuropraxia but an extremely low positive predictive value (0.2%). Another study in professional American football athletes confirmed the low positive predictive value of the Torg ratio for the presence of true spinal stenosis precluding its use as a screening tool for stenosis.¹⁹ Plain radiographs ignore the contribution of the soft tissue components that frequently cause stenosis, such as intervertebral disc protrusions, facet capsule hypertrophy, or ligamentous hypertrophy. Rather than defining stenosis by the canal dimensions, a more “functional” definition of stenosis may be that when the cerebrospinal fluid signal surrounding the cord is lost on magnetic resonance imaging (MRI) or computed tomographic (CT) myelography.²⁰

Klippel–Feil

Klippel–Feil abnormalities are characterized by congenital fusion of adjacent vertebral bodies. The fusion may only involve two levels or may be more complex with multiple adjacent segments involved or even noncontiguous segments. Restrictions on ability to participate in contact sports depend on which levels and how many levels are involved in the abnormal fusion. Furthermore, Klippel–Feil can commonly be associated with cardiac, renal, or other organ system abnormalities, which can further preclude participation in sports.

Cervical Disc Herniation

Cervical disc herniation is a career-threatening problem that can cause neck pain, radiculopathy, and/or myelopathy. It results in functional stenosis that cannot be appreciated with plain radiography alone, and depending on the extent and associated symptoms it can present a barrier to play. Players in sports that involve repetitive axial loading of the head and neck, such as American football, have been shown to have a higher incidence of cervical disc disease compared with the general population.²¹ Front-row rugby players also represent a high-risk population.²²

RETURN-TO-PLAY CRITERIA

Many published criteria exist for RTP; however, none of these are based on high-level evidence given the rarity of

the injuries. Almost universally these criteria are based on small retrospective case series and the educated opinion of experts in the field.

Stingers/Burners

Return-to-play decision making after a stinger should consider the severity of the symptoms, the number of episodes, and the timing of the episodes. After the first stinger or a second stinger occurring in a different season, the athlete can RTP immediately after the symptoms are resolved, and he or she has full, painless neck range of motion (ROM). If symptoms are persistent or do not completely resolve, the athlete should have further workup including imaging studies. After the second stinger occurring in the same season, the athlete should sit out the remainder of the game but can RTP the following game if symptoms have completely resolved and he or she has full, painless neck ROM. After the third stinger occurring in the same season, the athlete should sit out the remainder of the game regardless of severity or duration of symptoms. If symptoms are severe, the player should sit the remainder of the season. Furthermore, the athlete should have a full clinical and radiographic evaluation for the underlying etiology (e.g. congenital stenosis). Strong consideration should be given to restricting the athlete from contact sports if he or she has persistent or severe symptoms.

Transient Quadripareisis

Any athlete with an episode of transient quadripareisis warrants a full radiographic and clinical evaluation with X-rays and an MRI to evaluate for cord injury, stenosis, and/or underlying cord parenchymal abnormality (cord signal change). If there is no stenosis or cord parenchymal injury or abnormality, the athlete can RTP once he or she is asymptomatic and has full, painless neck ROM. If there is mild or moderate stenosis without evidence of cord injury and the athlete quickly recovers pain-free neck ROM, there is a relative contraindication to return to contact sports. The decision on whether the athlete ultimately can RTP is complex and must be made after a careful discussion between the athlete and his or her physician, in addition to any other involved parties. Important factors to consider are the severity and duration of the episode, the type of sport and the position played, and the level of play (high school, collegiate, and professional). If the athlete has severe stenosis or if there has been more than a single episode of transient quadripareisis, there is an absolute contraindication to return to contact sports.

For most spine practitioners, this scenario involves a student athlete who is accompanied by his or her parent. In such cases, we tend to have a stricter RTP criterion because of the medico-legal implications. The parents must be present and notified of the potential for permanent injury. Although there is scant evidence that transient quadriplegia is a predictor of permanent quadriplegia in the future, we make it clear to the parents that the absence of proof is not proof of the safety of returning to play. On the contrary, the argument for returning to play is that the overwhelming majority of those who suffer a permanent SCI have never had an episode of transient quadriplegia. Nonetheless, we explain that while the risk of an athlete suffering an SCI is low, if it happens to their child, it is 100% and likely permanent. Medicolegally, it is imperative that the parents are present and that all clinic visits are well documented. Even with a thorough discussion regarding the risks of returning to play, a lawsuit is highly likely if the surgeon “clears” the patient to return and the child subsequently suffers a permanent injury.

Cervical Fractures

In cases of cervical fractures, there is an absolute contraindication to RTP for a minimum of 10–12 weeks after the injury to allow for bony healing. While the athlete may be able to train after 6–8 weeks, depending on the fracture and the fixation, contact sports can result in refracture, even with stable flexion-extension views. We recommend obtaining a CT scan to document healed fracture, followed by maximal flexion-extension radiographs to document stability prior to allowing RTP. The RTP criteria depend on the type of fracture and the subsequent operative or nonoperative treatment. The function of the cervical spine is threefold: (1) to provide structural support for the soft tissues of the head and neck, (2) to allow for positioning of the head in three-dimensional space, and (3) to protect the spinal cord and cervical nerve roots. If the traumatic injury or subsequent treatment compromises any of these functions then the athlete has an absolute contraindication to return to contact sports. With this in mind, absolute contraindications for RTP include atlanto-occipital fusion, odontoid abnormalities, C1-C2 instability or fixed rotatory deformity, spear tackler’s spine, dynamic subaxial instability (>3.5 mm translation or $>11^\circ$ angulation), sagittal malalignment, trauma-induced canal compromise from retropulsed bony canal fragments or a herniated disc, persistent neurologic deficit, or >2 fused motion segments.²³

Relative contraindications to RTP include healed upper cervical spine fractures (nondisplaced Jefferson’s fractures, healed type I and type II odontoid fractures, healed lateral mass fractures of C2), healed minimally displaced compression fractures, healed fracture of the posterior elements (excluding spinous process fractures), or a healed one- or two-level anterior or posterior cervical fusion.²³ This is provided that the patient is pain free, has full ROM, and has no neurological deficits. Injuries that present no contraindication to RTP include healed spinous process avulsion fractures or healed nondisplaced subaxial fractures once the athlete has painless full ROM, and has regained strength and coordination in the head and neck.

We counsel players that these recommendations are not based on scientific evidence or large-scale clinical trials. However, they have been in use for >15 years and are generally agreed upon by experts in the field.

Stenosis

Given that contact athletes are not routinely screened for cervical stenosis, the diagnosis is usually made after the athlete has suffered a stinger with prolonged symptoms, had an episode of transient quadriparesis, or sustained another injury for which cervical spine imaging was obtained. In an athlete in whom the diagnosis of cervical stenosis is truly made incidentally with no neck symptoms and no neurological deficit, there is no contraindication to RTP. However, in any patient being worked up for neck pain, or radiculopathy with imaging findings consistent with either congenital or acquired stenosis, they have a relative contraindication to RTP. We believe that myelopathy due to congenital stenosis and not a large disc herniation that can be surgically treated is a contraindication to RTP. Many professional football players have a narrowed canal. We inform them that the presence of stenosis puts the athlete at a higher risk for neurological injury with any force imparted to the cervical spine. Any decision to return to sport must only be made after a full and informed discussion with the athlete, parents, and any other involved parties.

Cervical Disc Herniation

As described previously, cervical disc herniations may cause functional spinal stenosis and can place the athlete at higher risk of neurological injury following trauma involving the head and neck. Therefore, any athlete with

a known history of cervical disc herniation must be evaluated and examined carefully prior to allowing the patient to participate in contact sports. Furthermore, the athlete must be counseled that he or she has an increased risk of neurological injury with trauma compared with someone without a disc herniation. If a patient has a truly asymptomatic disc herniation, with no signs of radiculopathy or myelopathy on physical examination, he or she can RTP if he or she has painless cervical spine ROM. If a patient has a symptomatic disc herniation with neck pain, decreased ROM, radiculopathy, or myelopathy he or she should not be allowed to participate in contact sports.

After Anterior Cervical Discectomy and Fusion

Single-level cervical spine surgery for disc herniation in the general population has almost universally good to excellent outcomes; however, the demands placed on a fused cervical spine by athletes are quite different from that of the general population. Especially in American football, where numerous high-energy loads are transmitted to the head and neck each game, athletes are at high risk for cervical spine injury especially if they have had prior operative intervention. There is some data available on the outcomes of RTP for National Football League American (NFL) football players after cervical spine surgery. Hsu²⁴ showed that 72% of players successfully returned to play for an average of 2.8 years after single-level cervical spine surgery. However, because the data collection was based on publicly available information, only 60% of these players were confirmed to have had an anterior cervical discectomy and fusion (ACDF). More recently, Maroon et al.²⁵ reported their series of 15 NFL football players who underwent single-level ACDF and found that 13 of 15 were able to RTP at a mean of 6 months postoperatively. The RTP duration for those who retired after full participation ranged from 1 to 3 years. An analysis of 19 professional rugby players who underwent ACDF for symptomatic disc herniation showed that 68% returned to play at the same level of competition, with the majority returning by 6 months.²² Two players had recurrent symptoms with one being forced to retire. Although sparse, the published data support that athletes in contact sports can successfully RTP after a one- or two-level ACDF once the fusion has healed and they demonstrate painless, full neck ROM. Because of the increased lever arm and subsequent higher risk of neurological injury, an athlete should be restricted

from return to contact sports after a three- or more level ACDF. It is imperative to ensure that athletes have achieved a solid arthrodesis based on CT imaging prior to allowing them to RTP.

Cervical Disc Arthroplasty

To our knowledge, there is no published data on RTP after cervical disc arthroplasty. However, Tumialan et al.²⁶ did report on return to active duty in military personnel, a patient population that places high physiological stress and demand on their cervical spines similar to athletes. In their series, 12 patients (seven Navy SEALs, one marine, one landing craft air cushion engineer, and three high-ranking officers) underwent cervical arthroplasty, all of whom returned to unrestricted full duty by 3 months. The activities they were able to participate in by 3 months included parachute jumping, high-impact water entries from helicopters, diving, and long-distance runs while carrying a load. The arthroplasty group was compared with a similar cohort who underwent a single-level ACDF and found that the average time to unrestricted full duty for the arthroplasty group was shorter than that for the fusion group (10.3 weeks vs. 16.5 weeks, $p = 0.008$); however, this difference likely reflects the fact that fewer postoperative restrictions were placed on the arthroplasty group compared with the arthrodesis group rather than truly faster recovery. In this military series, their algorithm allowed for return to full unrestricted duty by 3 months. They allowed nonimpact training as soon after surgery as they were comfortable to do so, typically within the first month. In the second month, they were allowed to do light-impact activities and light weight training. Provided they remained asymptomatic, they were allowed to progress to high-impact training by the third month. It is our opinion that a single-level arthroplasty is as stable as an arthrodesis for most sports except high-impact sports such as American football.

Klippel-Feil

Klippel-Feil abnormalities are functionally similar to anterior interbody fusions and have similar barriers with regard to RTP. With one- or two-level Klippel-Feil abnormalities that do not involve the occipito-cervical junction or the C1-C2 articulation, there is no contraindication to RTP as long as the athlete has full, painless neck ROM. Athletes with fusions of three motion segments or greater should be restricted from participating in contact sports.

CONCLUSION

Cervical spine injuries are heterogeneous ranging from those with minimal to no sequelae on one end of the spectrum to complete quadriplegia on the other end of the spectrum. Each injury must be evaluated in the context of the athlete's unique cervical spine anatomy (i.e. patent canal vs. stenotic) with regard to the physical demands required for the athlete's particular sport and position. Stingers and burners are extremely common, and patients can typically RTP quickly after symptoms subside following a first-time event. Return to play is more variable and occurs at a lower rate following transient quadriplegia or ACDF. Ultimately, an individualized approach to each injury is necessary and must be carried out with the full informed consent of the athlete and all involved parties. Medicolegal issues must be kept in mind when making decisions.

KEY POINTS

- Stingers and burners are incredibly common in athletes and may be underreported. Athletes can RTP after a first episode once asymptomatic and have recovered full strength.
- Transient quadriplegia is a more serious injury and a careful workup should be performed to rule out intrathecal pathology or severe canal stenosis with prolonged symptoms.
- Athletes can successfully RTP after one- or two-level ACDF.
- All cervical spine injuries mandate an individualized approach for appropriate treatment and RTP assessment.

INTRODUCTION

The upper cervical spine, or occipital-cervical junction (OCJ), includes the osseous, ligamentous, and neurovascular structures that extend from the occiput to C2. This is a very mobile functional segment, thus injuries are quite common as with other transitional spinal segments at the cervicothoracic and thoracolumbar junctions. The large moment arm produced by the cranium on the inherently unstable osseous structures is borne by specialized ligaments making this area particularly prone to injury. Due to the presence of vital neurovascular structures, injuries to the upper cervical spine can be fatal and are a common finding on autopsy of blunt trauma deaths.¹⁻⁴ Improvements in automobile safety and trauma care have increased survival of the inciting trauma, making diagnosis and management of the constellation of injuries to the OCJ increasingly more common. This chapter will describe the functional and surgical anatomy of the OCJ, the epidemiology, evaluation, and evidenced-based management of the following injuries to the OCJ: occipital condyle fractures, occipital-cervical dissociation, atlas fractures, traumatic atlanto-axial instability, odontoid fractures, and traumatic spondylolisthesis of the axis.

ANATOMY

The upper cervical spine is responsible for approximately 60% of the total axial rotation of the cervical spine, 40% of total flexion and extension, and 45% of overall cervical motion.^{5,6} The bony components include the occiput with its bilateral condyles, the atlas (C1), and the axis (C2) with its large cranial projection, the odontoid process. The associated capsulo-ligamentous structures are responsible for providing increased restraint and stability to this highly mobile area, thus protecting the brainstem and spinal cord. The unique osseoligamentous anatomy of the upper cervical spine is demonstrated in the spectrum of injuries unique to the area. A thorough understanding of this anatomy is paramount to the evaluation and treatment of upper cervical spine injuries.

There are two articulations between the occiput and atlas providing the bony support for the cranium on the axial skeleton. The oval-shaped occipital condyles articulate with the concave superior articular facets of C1 in a shallow ball and socket articulation. These paired joints are sloped $30 \pm 7^\circ$ in the coronal plane⁷ inferiorly toward the midline allowing for 20° – 30° of flexion and extension, 5° – 10° of lateral bending, but little to no axial rotation.⁸⁻¹⁰ The atlas and axis have four synovial articulations. The

Fig. 53.1: Illustration depicting the bony and ligamentous anatomy of the upper cervical spine.

superior facets of C2 articulate bilaterally with the broad, shallow inferior facets of the atlas. The posterior aspect of the anterior arch of C1 articulates through a synovial joint with the anterior aspect of the odontoid process. There is a secondary synovial articulation between the posterior aspect of the odontoid process and the transverse atlantal ligament (TAL). Together, approximately 60% of the total axial rotation of the cervical spine occurs through these C1-C2 articulations. In this function, C1 serves as a washer between the occiput and C2, with ligamentous structures providing for controlled motion of C1 and C2.

There are many ligamentous structures associated with the upper cervical spine. The ligamentum flavum, ligamentum nuchae, and anterior and posterior longitudinal ligaments are analogous to, or continuations of, similar structures in the subaxial spine. Those structures unique to the upper cervical spine include the cruciform ligament, the alar ligaments, apical ligament, tectorial membrane, and the anterior and posterior atlanto-occipital membranes (Fig. 53.1).

The apical ligament lies in the space between the anterior atlanto-occipital membrane and the cruciform

ligament spanning from the tip of the odontoid to the anterior aspect of the foramen magnum. It has no specific role in stabilizing the OCJ. The anterior and posterior atlanto-occipital membranes span from the anterior and posterior aspects of C1, respectively to the foramen magnum defining its extent. The tectorial membrane is a broad expansion of the posterior longitudinal ligament that originates on the posterior body of C2 and inserts bilaterally on the anterolateral edge of the foramen magnum. Along its course it shares fibers to reinforce the lateral C1-C2 facet joint capsules. The exact function of the tectorial membrane is unknown. It has been hypothesized that it limits axial distraction of the OCJ, restrains flexion of the occiput-C1 articulation, and provides protection against compression of the thecal sac and spinal cord from the anteriorly located odontoid.¹¹⁻¹³

The most important ligamentous structures of the OCJ are the alar ligament and the transverse portion of the cruciform ligament. The paired alar ligaments originate on the dorsolateral surface of the odontoid and travel obliquely to insert on the lateral mass of C1 and the inferomedial occipital condyle. The alar ligaments help maintain the position of the odontoid relative to C1 and are the primary restraint to axial rotation of both the atlanto-occipital and atlantoaxial segments with some effects on lateral bending and flexion.^{11,12,14} They are slack in the neutral head position and during rotation the alar ligament on one side tightens allowing up to 90° of rotation to the contralateral side. Sectioning of a single-sided alar ligament in cadaveric specimens resulted in increased flexion and contralateral lateral bending at occiput-C1 and increased flexion, extension, and rotatory instability at C1-C2.^{8,9} Sectioning of the second ligament resulted in little change. The cruciform ligament is composed of both a vertical component and a transverse component. The vertical component spans from the posterior body of C2 to the clivus superiorly. The transverse component, known as the TAL, attaches to the medial aspect of the C1 lateral mass traveling posterior to the odontoid process holding the odontoid to the anterior arch of C1. It serves to limit flexion, extension, translation, and bending of the C1-C2 articulation while allowing for rotation. At 6–7 mm in thickness and height, it is the largest ligament of the OCJ, the primary stabilizer of C1¹⁵ and, with a load to failure of 350 N, is 66% stronger than the alar ligaments.⁵

■ EPIDEMIOLOGY

A large meta-analysis demonstrated an overall prevalence of cervical spine injuries of 3.7% in all blunt trauma

patients and 7.7% in obtunded patients, with 41.9% of cervical spine injuries exhibiting instability.¹⁶ Upper cervical spine trauma occurs in a bimodal distribution with a preponderance of injuries occurring in pediatric patients and in those over 60 years of age. Children under age 7 with cervical spine injuries are most likely to have been injured in a motor vehicle crash (MVC) and 74–80% of the injuries are at the OCJ.^{17,18} Adolescents aged 8–15 with cervical spine injuries are equally likely to be injured in an MVC as they are playing sports, with 47% of cervical spine injuries occurring at the OCJ. The mortality rate for these injuries is between 7% and 25% with the higher values including those with concomitant closed head injury. In comparison to children, fractures of the upper cervical spine in those over 60 years of age are more likely to be caused by low energy falls (45–100%) than high energy MVC. Nearly 70% of all cervical spine fractures in this age group occur at the OCJ, with up to 60% of the injuries occurring to the odontoid process.¹⁹⁻²¹

■ EVALUATION

The evaluation of the blunt trauma patient should proceed as always according to Advanced Trauma Life Support protocol to minimize the risk of failure to identify significant injuries and to stabilize the hemodynamically unstable patient. Care should be taken to maintain strict spinal precautions and bracing until the patient can be examined both clinically and with imaging. Failure to appropriately diagnose upper cervical spine injuries in a timely fashion can result in precipitous neurologic deterioration and death.^{22,23}

Imaging

Historically, plain radiography of the cervical spine, including anteroposterior, lateral, and open mouth odontoid views has been considered an integral part of the evaluation of the blunt trauma patient. Most injuries of the OCJ can be appreciated on plain radiography; however, they are inadequate to fully characterize the OCJ secondary to projectional and rotational issues.^{24,25} One series demonstrated an 8% rate of occipital condyle, atlas, and axis fractures that were not apparent on lateral radiographs.²⁴ Increases in the prevertebral soft tissue shadow may indicate an injury. The anterior soft tissue shadow on lateral radiography should be approximately 6 mm at C2 and 20 mm at C6. Increases from these values should prompt the use of more advanced imaging modalities.

Computed tomography (CT) of the cervical spine with axial, sagittal, and coronal three-dimensional (3D) reconstructions have largely replaced plain radiography in the evaluation of the upper cervical spine in blunt trauma patients due to the high sensitivity, specificity, and cost efficacy in detecting injuries.²⁶⁻²⁸ Extensive normative data has been produced to assist in detecting subtle instability even in the absence of fractures.^{29,30} Raza et al. showed that normal CT scans of the cervical spine have a negative predictive value of 99.7% for clinically significant cervical spine injury even in obtunded patients.³¹ Purely ligamentous injuries of the cervical spine are quite rare, and most can be detected by CT or plain radiography and do not require the use of magnetic resonance imaging (MRI).^{32,33}

Magnetic resonance imaging is the ideal imaging modality for evaluating the soft tissue structures of the OCJ. Though multiple studies have shown CT to consistently rule out clinically significant cervical spine injuries including instability, there remains a utility for characterizing the soft tissue structures in combined bony and soft tissue injuries of the OCJ when purely bony injuries could be treated with an orthosis or halo-vest. Waiting for upright plain radiography or MRI in obtunded patients increased the length of time spent in cervical collar with spinal precautions in obtunded trauma patients by 2.4 days and did not detect any previously undiagnosed injuries in patients with negative multidetector CT scan.³³ A fluoroscopically visualized, surgeon-controlled, axial traction test has been proposed for evaluating for instability related to ligamentous injury but has not been validated.³⁴ In addition, flexion and extension radiographs have been used to evaluate those with negative radiography and CT imaging, though studies have shown no increased detection rates.³⁵

■ OCCIPITAL CONDYLE FRACTURES

Fractures of the occipital condyle were first described by Bell in 1817.³⁶ They are most commonly unilateral and are found in 1–3% of all OCJ injuries.³⁷ They are routinely associated with closed head injury and cranial nerve injuries due to the proximity of cranial nerves VI, IX, X, XI, XII.³⁸ Fractures of the occipital condyle are often stable injuries and may be treated nonoperatively with cervical collars, noninvasive cervicothoracic orthoses, or halo-vest immobilization. Evaluation of ligamentous integrity is the key to determining treatment strategy.

Saturnus first attempted to classify occipital condyle fractures by force vector, utilizing autopsies to identify six distinct fracture patterns.³⁹ This system was refined by

Anderson and Montesano in 1988 when they proposed classifying the fractures into three distinct morphological types.⁴⁰ Type I fractures are comminuted fractures of the occipital condyle, are most commonly unilateral, and are the result of an axial load. Type II fractures are fractures of the base of skull, may be bilateral, and are often the result of a direct blow to the head causing the condyle to shear. They may leave the condyle free floating from the base of the skull. Type III fractures are avulsion fractures of the inferomedial occipital condyle involving the attachment of the alar ligament. They are the result of combined lateral bending and rotation forces. The determination of stability of the occiput-atlas articulation is the key to management. Bilateral injuries are more likely to be unstable.

The majority of isolated occipital condyle fractures without malalignment or associated atlanto-occipital instability can be treated in a cervical collar or more restrictive orthosis such as a Minerva or sternal occipital mandibular immobilizer (SOMI) though studies in healthy volunteers have showed minimal difference in motion restriction between the specific orthoses.⁴¹ Nonoperative management of stable fractures is successful for healing of fractures in >90% without risk of secondary dislocation.⁴² Nonoperatively treated OC fractures are associated with mild to moderate neck disability as measured by the neck disability index regardless of gender; patients aged 40–60 tend to do slightly worse.^{42,43} In a retrospective review from a single level I trauma center, Maserati et al. reported on the successful nonoperative treatment of all occipital condyle fractures without associated atlanto-occipital instability or malalignment in a cervical collar or SOMI brace.⁴⁴

The decision for operative management is based on stability and alignment. Type II injuries with displacement of the atlanto-occipital articulation should be treated with reduction and halo-vest application under fluoroscopy. Occasionally, occipitocervical fusion may be required if closed reduction cannot be achieved. Type III injuries with instability and/or displacement should be treated with occipitocervical fusion.

■ OCCIPITOCERVICAL DISSOCIATION

Occipitocervical dissociation is associated with high mortality rates.³ Improvements in trauma care and diagnostic imaging have increased both the rate of detection and the survivability of these injuries. They are frequently associated with craniofacial and closed head injuries.⁴⁵ Atlanto-occipital injuries are more common in the pedi-

ric population due to more horizontally oriented atlanto-occipital facets and their increased head to body weight ratio. These relatively uncommon, highly unstable injuries are most commonly caused by distraction and hyperflexion or extension in high energy blunt force trauma.

Traynelis proposed a classification of atlanto-occipital dislocations based on the direction of displacement.⁴⁶ Type I injuries exhibit anterior displacement of the occiput relative to the cervical spine. Type II injuries exhibit distraction of the atlanto-occipital joints in which <2 mm distraction is considered normal. Type III injuries are dorsal displacement and type IV injuries are complex. While this classification describes the appearance of the injuries it does not provide prognostic information or treatment guidance.

Several methods have been developed for detecting these injuries on plain radiographs and many have been adapted to nondistorted sagittal reconstructions of CTs. Harris lines include the basion-axis interval (BAI) and basion-dens interval (BDI) that are both <12 mm in normal subjects.²⁵ The Wackenheim clival line runs tangential to the posterior cortex of the clivus and should pass within 1–2 mm of the posterior tip of the dens and is indicative of a reduced OCJ (Fig. 53.2).⁴⁷ Powers Ratio is based on the relationship between the basion and the posterior arch of the atlas compared with the relationship between the opisthion and the anterior arch of the atlas.⁴⁸ A ratio of 0.77 is considered normal and >1 abnormal, indicating anterior dislocation; however, utilization may produce false negatives in type II or III injuries (Fig. 53.3).⁴⁹ The revised occi-

Fig. 53.2: Representation of the basion-axis interval (BAI) and the basion-dens interval (BDI). Values >12 mm should raise suspicion for atlanto-occipital dissociation.

Fig. 53.3: Representation of the Wackenheim Clival Line (WCL) that should pass within 1–2 mm of the posterior tip of the dens, indicating a reduce occipitocervical junction. Powers Ratio (A/B) can be used to assess for an anterior atlanto-occipital dislocation. A ratio of 0.77 is normal with >1 being abnormal.

pital condyle-C1 interval measures the maximum distance between the occipital condyle and the lateral mass of C1 on a mid-sagittal CT view, and has been shown to have excellent inter-rater reliability.⁵⁰ It is considered abnormal if >2.5 mm and careful consideration of advanced imaging should be considered. Prior studies have shown significant uniformity in the congruency of the atlanto-occipital articulation with a mean separation of 0.6 mm.³⁰

The Harborview classification of occipitocervical dislocation as proposed by Bellabarba et al. includes both primary atlanto-occipital distraction, as well as C1-C2 distraction, C1-C2 translation, and combined patterns.⁴⁵ It classifies these injuries according to stability and subsequent treatment strategy by assessing CT, MRI, and if indicated traction radiography. The BAI and BDI are the originally described diagnostic criteria. Type 1 injuries have negative CT findings, positive MRI findings of non-displaced ligament injuries and can be treated with a cervical orthosis. Type 2 injuries have normal CT findings, positive MRI findings of ligament injuries, and a positive traction test, which indicates spontaneous reduction of the dislocation but underlying instability. They can be treated successfully with halo-vest if reduction can be maintained, though late displacement may require posterior fusion. Type 3 injuries demonstrate gross instability on both CT and MRI. They should be treated initially with immediate halo-vest application and definitively with posterior cervical arthrodesis to include the occiput if necessary (Figs. 53.4A to F). Caution must be exercised with the use

Figs. 53.4A to F: A 22-year-old man sustained an unstable craniocervical dissociation without fracture in an auto versus pedestrian accident. (A, B, and C) Axial and sagittal computed tomography cuts demonstrating incongruity of the occiput—C1 articulation, widening of the occiput-C1 and C1-C2 facets, and increased atlanto-dens interval (ADI), respectively. (D) T2-weighted sagittal magnetic resonance imaging sequence demonstrating increased ADI. (E and F) Open mouth and lateral radiographs following occiput to C2 fusion with C1-C2 transarticular screw-occipital plate construct and Gallie graft wiring.

of cervical collars in these dissociative conditions as they have been shown to cause distraction of the upper cervical spine.^{45,51}

■ ATLAS FRACTURES

Atlas (C1) fractures account for approximately 5% of all cervical spine injuries and a quarter of all injuries to the atlantoaxial complex.⁵² Jefferson first described atlas fractures in 1921. The eponymous Jefferson fracture is characterized by bilateral fractures in the anterior and posterior arches of the C1 ring and constitutes the most common C1 injury pattern. It is often the result of an axial load with or without lateral bending and is highly associated with head injury and/or other cervical spine injuries.^{52,53} Other C1 injury patterns include isolated anterior or posterior arch fractures, transverse process fractures, or lateral mass fractures.

The most important factor guiding treatment of C1 fractures is an assessment of stability. The two most common radiographic measurements utilized are the lateral mass overhang and atlanto-dens interval (ADI). Combined lateral mass overhang on the open mouth view should be <7 mm.⁵⁴ Widening >7 mm indicates transverse ligament rupture and instability necessitating stabilization. An ADI >3 mm in adults and >5 mm in children is also indicative of a transverse ligament rupture.⁵⁵ The integrity of the TAL can also be assessed directly with MRI.

The majority of isolated nondisplaced C1 fractures can be safely treated with a rigid collar.⁵⁶ Jefferson burst type fractures with mild displacement can be treated in a cervicothoracic orthosis such as a SOMI or Minerva or with halo-vest immobilization. Initial closed reduction with traction and halo-vest application for 3 months can be considered for fractures with <7 mm displacement with flexion-extension radiographs obtained upon halo removal. If instability is present at that time then C1-C2 arthrodesis should be performed (Figs. 53.5A to F). Multiple complications have been reported with long-term use of halo-vest immobilization including loss of reduction with cranial settling, pin-site infection, intracranial abscess, and pulmonary compromise.⁵⁷ Recently, immediate surgical stabilization has been the preferred method of treatment to avoid the morbidity of long-term halo-vest immobilization.

The most commonly used methods of surgical stabilization include C1-C2 screw and rod constructs, as initially described by Harms,⁵⁸ and C1-C2 transarticular screw fixation, as initially described by Grob and Magerl.⁵⁹

Posterior wiring can be included if the posterior arch is intact. These procedures require traction to reduce the spread of the lateral masses prior to instrumentation and can be technically demanding. Occasionally, occiput to C2 fusion is required if O-C1 instability is present or anatomic considerations such as lateral mass fractures preclude C1 lateral mass fixation. Due to the morbidity of loss of motion at the C1-C2 segment, motions preserving direct C1 ring osteosynthesis procedures have been developed. Transoral reduction of the lateral masses with anterior fixation has been reported but is technically difficult and carries a high risk of infection.^{60,61} Motion preserving posterior procedures have been reported as well involving closed reduction with traction and subsequent lateral mass screw placement connected by a transverse rod.⁶² Koller et al. demonstrated in a biomechanical study that primary C1 ring osteosynthesis does not result in any increased C1-C2 instability even in cases of known transverse ligament rupture.⁶³

■ TRANSVERSE LIGAMENT RUPTURE

The transverse ligament rupture (TAL) is the primary stabilizer of the atlanto-odontoid articulation. As with most ligaments in the body, primary healing is unlikely with injury. Integrity of the TAL is the largest determinant of stability in atlas fractures and subsequently stability of the atlantoaxial complex. While rare, isolated injuries are possible and can be diagnosed by plain radiographs or CT, using the ADI as described above, or by assessment with MRI. Occasionally flexion-extension radiographs of the upper cervical spine may be required.

Ruptures of the TAL were classified by Dickman et al. into two types based on the location of the rupture.⁶⁴ Intrasubstance ruptures are subdivided into midportion (Type 1a) versus periosteal (Type 1b) ruptures. Rupture associated with avulsion fractures are subdivided based on the presence of a comminuted (Type 2a) or intact (Type 2b) C1 lateral mass. Type 1 injuries with static or dynamic instability should be treated with atlantoaxial fusion. Options for C1-C2 fusion are anterior screw fixation, posterior instrumentation with segmental screws, C1-C2 transarticular screws, and posterior C1-C2 wiring with autograft.

Historically, C1-C2 posterior wiring as described by Brooks or Gallie was the primary means of obtaining C1-C2 arthrodesis. C1-C2 posterior wiring alone requires the use of a halo-vest postoperatively, has a high rate of nonunion,

Figs. 53.5A to F: This patient sustained a Jefferson fracture in a motorcycle accident. (A) Axial computed tomography (CT) scan at C1 shows burst fracture of C1 with minimal displacement and likely avulsion fracture of transverse atlantal ligament. (B) Sagittal CT scan shows atlanto-dens interval within normal limits. (C) Upright open mouth and (D) Lateral radiographs in cervical orthosis demonstrates C1-C2 instability. (E and F) Cervical radiographs approximately 2 years status post-C1-C2 posterior instrumented fusion.

and is less biomechanically stable than constructs using screws; however, it has been shown to be an efficacious adjuvant to improve both fusion rates and stability.^{65,66} Either C1-C2 transarticular screws or C1 lateral mass, C2 pedicle or pars screw-rod constructs may be used. Transarticular screws place the vertebral artery more at risk particularly in the setting of a high riding vertebral artery. Naderi et al. demonstrated in a cadaveric biomechanical study that transarticular screw constructs were superior to posterior cable grafting with respect to lateral bending and axial rotation, but posterior cable grafting provided better control of flexion and extension.⁶⁷ The strongest construct was posterior cable-graft with bilateral transarticular screws. Melcher et al. demonstrated that posterior screw rod constructs were biomechanically equivalent to transarticular screws in a cadaver model.⁶⁸ Transarticular screw placement may not be possible for a number of reasons, including: an anomalous medial course of the vertebral artery present in 20% of the population, incongruity of the atlantoaxial joints, and severe thoracic kyphosis precluding appropriate starting point and approximately 65° screw trajectory.⁶⁹⁻⁷¹ Due to the significant anatomic variability of C2 and aberrant course of vertebral artery, C2 pedicle screws may not always be safely possible. In cases in which the anatomy limits placement of bilateral C2 pedicle screws, a construct using a unilateral C2 pedicle screw with a contralateral short pars screw is a viable option and compares favorably with a bilateral C2 pedicle screw construct.⁷² Fixation in C2 with the use of crossed transaminar screws has also been shown to compare favorably to C2 pedicle screws.⁷³

■ TRAUMATIC ROTATORY ATLANTOAXIAL DISLOCATION

Rotatory atlantoaxial subluxation or dislocation is often atraumatic and is well described in the pediatric population and in association with Down's syndrome, Marfan's syndrome, inflammatory arthritides, and Grisel's syndrome. Traumatic atlantoaxial dislocation or subluxation without fracture, however, is an uncommon clinical entity. It was first described in 1969 by Haralson and is often the result of a motor vehicle accident.⁷⁴ Patients will typically present with pain and/or torticollis. Plain radiography may indicate asymmetry of the lateral masses on open mouth view or increased ADI on the lateral. Often CT is required to diagnose and 3D volumetric reconstructions are especially helpful in detecting subtle rotational malalignment and in verifying reduction. Cadaveric- and MRI imaging-based

studies have demonstrated ruptured atlantoaxial facet capsules with subsequent failure of the alar ligaments to be the likely pathologic cause.^{75,76}

The most commonly used classification system was described by Fielding and Hawkins and is based on the direction of rotation and displacement.⁷⁷ Type I is purely rotatory with the odontoid as a pivot point and can occur without ligament rupture. Type II is rotatory with the lateral mass as a pivot point and usually is associated with a transverse ligament rupture resulting in an increased ADI. Types III and IV are anterior or posterior dislocation of the atlas.

Closed reduction with skeletal traction via cranial tongs is the treatment of choice in acutely diagnosed injuries. Stable reductions can be treated in a hard cervical collar for 8–12 weeks. Those with difficult closed reductions or subtle instability should be treated with a halo-vest. Unreducible dislocations require open reduction and C1-C2 arthrodesis. Even in patients with successful, stable closed reductions, range of motion is likely to be reduced and they may have persistent occipital neuralgia.⁷⁸

■ ODONTOID FRACTURES

Fractures of the odontoid process of C2 account for >40% of all C2 fractures, 10–15% of all cervical spine fractures, and are the most common fracture of the upper cervical spine in those over 65 years of age.⁷⁹ These injuries occur most commonly in young males following high energy trauma and in the elderly following ground level falls. While they can occur as a result of a number of biomechanical mechanisms, the most common etiology in the elderly is hyperextension in fall as a result of a posteriorly directed blow to the head. These injuries can be diagnosed on open mouth and lateral radiographs but nondisplaced injuries may require thin-cut CT images for diagnosis.

Odontoid fractures were classified by Anderson and D'Alonzo into three types based on the location of the fracture line.⁸⁰ Type I fractures occur at the tip of the odontoid, above the TAL, and are a result of an alar ligament avulsion. They are stable injuries that can be treated in a hard cervical collar. Type II fractures occur at the waist of the odontoid in the area covered by the TAL. Type III fractures extend into the body of C2. Grauer et al. modified the type II fractures based on the orientation of the fracture line in order to stratify treatment options.⁸¹ Type IIa fractures are nondisplaced. Type IIb injuries exhibit a fracture line running obliquely from anterior-superior to posterior-inferior. Type IIc fractures are comminuted or have fracture lines running anterior-inferior to posterior-superior.

Type I fractures that are stable can be treated in a cervical collar, however, if occipitocervical instability is present then arthrodesis is required. Type III fractures are amenable to nonoperative treatment due to the large bony surface area for healing to occur; however, they are unstable injuries and should be treated in a cervicothoracic orthosis or halo-vest. Nonunion or inability to maintain alignment are indications for C1-C2 arthrodesis.

Type II fractures are unstable injuries and must be treated accordingly. Due to the vascular watershed in this area of the odontoid, nonunion rates are approximately 30%.⁸² Risk factors for nonunion are age > 50, displacement > 6 mm, angulation > 10°, and residual displacement of >2 mm following halo-vest application.^{83,84} In young patients, these injuries can be treated in a halo-vest if alignment can be maintained; otherwise they are treated with instrumentation (Figs. 53.6A to F). This is especially true for nondisplaced (type IIa) injuries. In the acute setting, type IIb injuries can be surgically treated with an anterior odontoid screw placement, with healing rates reported as high as 96%,⁸⁵ or via posterior C1-C2 instrumented fusion. Anterior screw fixation is advantageous in this select subset of injuries as it can preserve motion at C1-C2. Anterior screw fixation should be undertaken cautiously in elderly patients as complication rates are high. Scheyerer et al. reported nonunions in 13 of 17 elderly patients treated with anterior fixation compared to a nonunion in 1 of 16 treated with posterior C1-C2 arthrodesis.⁸⁶ Vasudevan et al. reported high rates of postoperative pneumonia (30%) and dysphagia (43%) requiring supplemental feeding tube placement in a cohort of patients over 65 years of age treated with anterior screw fixation.⁸⁷ Type IIc injuries may be treated with either halo-vest or posterior C1-C2 fusion, but due to the orientation of the fracture planes are not amenable to anterior screw fixation.

Odontoid fractures in the elderly are predominantly type II and are associated with significant morbidity and an elevated risk of mortality similar to that of hip fractures. There is significant controversy over the best method for treating these injuries. Mortality rates have been reported to be between 10% and 57% in this group.⁸⁸ Tashjian et al. demonstrated a 42% mortality rate in elderly patients treated with a halo-vest and high rates of pneumonia due to the restrictive nature of a properly fitted vest.⁸⁹ The use of halo-vests should be avoided in elderly patients due to the significant impact on mortality. Treatment should either be a collar immobilization or posterior C1-C2 arthro-

desis utilizing the techniques described elsewhere in this chapter. Chapman et al. demonstrated in a cohort of 322 patients with type II odontoid fractures that surgical treatment significantly improved 30-day mortality with a trend towards improved long-term survival compared with nonoperative treatment.⁹⁰ Woods et al. found similar data with respect to 30-day mortality, but no difference between operative and nonoperative survival rates at 1 and 5 years.⁹¹ Mortality was most significantly related to the Charlson Comorbidity Index regardless of treatment. Prospective multicenter studies have shown that there is decreased mortality and improved functional outcomes in elderly patients undergoing surgical treatment. In those patients treated nonoperatively, 22% ultimately required surgery secondary to fracture nonunion.^{92,93} Interestingly, patients with nonunion did not report worse outcomes compared with those who achieved union at 12 months.⁹⁰ In patients with acceptable comorbidities, the trend is currently towards surgical stabilization.

■ TRAUMATIC SPONDYLOLISTHESIS OF THE AXIS

Traumatic spondylolisthesis of the axis, known colloquially as a Hangman's fracture, is a fracture through the neural arch of C2. They were initially classified by Effendi et al. with subsequent modification by Levine and Edwards.^{94,95} Type I injuries are bilateral fractures of the pars interarticularis as a result of hyperextension and axial load with <3 mm of translation and no angulation. Type II injuries are displaced (>3 mm) and angulated bipedicular fractures with discoligamentous injury as a result of hyperextension followed immediately by flexion. They may appear similar to Type I injuries on supine radiographs or CT, but will displace on upright radiographs as a result of the disc injury. Type IIA injuries have significant disc and posterior longitudinal ligament injury and will have significant angulation with minimal translation and may be associated with other cervical spine injuries as a result of a flexion-distraction force (Figs. 53.7A to D). Type III injuries include C2/3 facet dislocations and are highly unstable.

Type I injuries are stable and may be treated with a cervical orthosis for 12 weeks. Type III injuries commonly are unreducible by closed means and require surgical reduction via a posterior approach with subsequent C2-C3 or C1-C3 posterior instrumentation and arthrodesis. There is controversy surrounding the treatment of Type II and IIA

Figs. 53.6A to F: An 18-year-old man sustained a type 2 odontoid fracture that failed attempted closed reduction with a halo-vest. (A and B) Axial and sagittal computed tomography cuts demonstrating a Type IIc odontoid fracture with 8 mm of anterior displacement. (C and D) Lateral and open mouth radiographs following C1-C2 screw-rod construct placement without fusion. (E and F) Flexion and extension radiographs following removal of instrumentation after fracture healed.

Figs. 53.7A to D: This patient sustained an occipitocervical dislocation with associated type IIA Hangman's fracture. Initial treatment was in a halo-vest without reduction due to hemodynamic instability precluding immediate surgical stabilization. (A) Sagittal computed tomography cut demonstrating anterior occipital subluxation and Hangman's fracture (arrow). (B) Sagittal T2-weighted magnetic resonance imaging demonstrating C2/3 disc disruption (arrow) and spinal cord signal changes. (C and D) Anteroposterior and lateral radiographs demonstrating occiput to C3 posterior instrumented fusion.

injuries. Vaccaro et al. reported on a series of 31 patients with Type II or IIA injuries who were successfully treated with early reduction and halo immobilization.⁹⁶ Six out of 27 patients in the Type II cohort required revision reduction in traction due to delayed fusion and all were noted to have had an initial angulation of $>12^\circ$. Treatment in a halo may result in healing in a nonanatomic position leading some to advocate for surgical osteosynthesis or segmental fusion.⁹⁷ Excellent results have been shown with C2-C3 anterior discectomy and fusion as well as posterior C2-C3 instrumented fusion^{98,99} with a biomechanical study

showing them to offer similar stability.¹⁰⁰ Primary osteosynthesis of a type II fracture has been reported with direct repair with C2 pars screws.¹⁰¹ In cases where fixation cannot be achieved across the fracture at C2, extension to C1 may be required.

SUMMARY

Upper cervical spine injuries are common injuries that are increasing in numbers as trauma care and automobile safety improves. These injuries can be missed, especially

in purely ligamentous injuries, with the potential for neurologic deterioration. The use of thin slice multidetector CT as the gold standard for evaluation in blunt trauma patients has increased the detection of these injuries. Care must still be taken to evaluate for ligamentous injury. The algorithm for surgical versus nonsurgical management is based on displacement, stability, and the status of the soft tissue restraints.

KEY POINTS

- Upper cervical spine injuries are frequently diagnosed on a delayed basis with potentially severe neurologic sequelae.
- Multiple imaging studies, including radiographs, CT, and/or MRI may be required to fully evaluate the occipitocervical junction with thin slice CT best evaluating the bony structures and MRI evaluating the soft tissue structures.
- Nonoperative treatment is often the preferred method of treatment of osseous injuries without ligamentous instability such as most occipital condyle fractures, atlas fractures, traumatic spondylolisthesis of the axis, and odontoid fractures.
- Operative treatment is often reserved for injuries with purely ligamentous or combined osseoligamentous injuries with significant static or dynamic instability.
- The choice of fixation method in C1 and especially C2 must be based on the individual patient's anatomy due to the variability of both bony anatomy and vertebral artery course.
- Operative treatment of Type II odontoid fractures in the elderly is controversial; however, it is associated with fewer nonunions, better functional outcomes, and a lower 30-day mortality compared to treatment in a rigid cervical collar. Halo-vests should be avoided in the elderly.

EPIDEMIOLOGY

Subaxial cervical spine injuries account for 2–3% of all reported blunt trauma and two-thirds of cervical fractures and dislocations.^{1,2} Hu et al.² reported an annual incidence of 64 per 100,000 and identified a bimodal age distribution in young males and elderly females. The etiology of most subaxial trauma includes motor vehicle and transport incidents particularly in the younger population and accidental falls in the elderly.² Injuries to C6 and C7 contribute to the majority of lower cervical spine trauma¹ with most cases not resulting in neurologic or spinal cord injury (SCI).^{2,3}

The burden of cervical spine fractures has significant implications on lifetime disability, mortality, and health-care cost and utilization. Baaj et al.³ reported a 74% increase in hospitalizations following cervical spine fractures in the United States over a 10-year period compounded by a similar increase in total hospital charges from \$20,701 in 1997 to \$35,984 in 2006. During this period, no significant improvement in mortality was demonstrated despite considerable advancements in surgical and nonsurgical treatments.³

ANATOMY

The subaxial cervical spine extends from C3 to C7. Each motion segment consists of two subjacent vertebrae

connected by an intervertebral disk, posterior ligaments, and facet joints. Holdsworth et al.⁴ divided the cervical spine motion segments into two columns or elements. The anterior column consists of the anterior longitudinal ligament, anterior annulus, vertebral bodies, transverse processes, posterior annulus, and posterior longitudinal ligament. The posterior column consists of the ligamentum flavum, facet capsules, interspinous ligament, supraspinous ligament, pedicles, laminae, and the spinous processes.⁴ Facet joints are parallel to the frontal plane and 45° to the transverse plane. These contribute to the rotational stability of the subaxial cervical spine. The spinal cord is contained within the spinal canal limited anteriorly by the vertebral body, intervertebral disk, and PLL; posteriorly by the laminae and ligamentum flavum; and laterally by the pedicles and medial aspect of the facet joints. The average magnetic resonance imaging (MRI) anteroposterior and transverse diameters of the spinal cord vary from 8.8 mm × 12.4 mm at C2 to 8.7 mm × 14 mm at C4 and 7.4 mm × 11.4 mm at C7.⁵

DIAGNOSIS

During the initial evaluation, expedient cardiopulmonary resuscitation is of paramount importance while maintaining strict spinal precautions to avoid any iatrogenic neurological injury. Every trauma patient should be assumed

Table 54.1: NEXUS low-risk criteria.

<i>C-Spine radiography is not indicated if all of the following criteria are met</i>		<i>Notes</i>
No posterior midline C-spine tenderness	and	Tenderness extending from the nuchal ridge to T1
No signs of intoxication	and	History; odor of alcohol; ataxia; cerebellar dysfunction; slurred speech
Normal level of alertness	and	Glasgow Coma Score ≤ 14 ; disorientation; altered response to stimuli
No focal neurologic deficit	and	Sensory or motor deficits on neurological examination
No painful distracting injury		Fractures; organ injury; laceration; crush injury; burn

to have a cervical SCI until proven otherwise. A detailed survey of the face, cranium, and entire spine must be performed to appreciate physical signs of injury including pain upon palpation, ecchymoses, widened interspinous spaces, sagittal deformity, acute kyphosis, or loss of cervical lordosis. A thorough neurovascular examination in all extremities is pivotal to evaluate neurologic compromise during the secondary survey. In a study of 52 patients with a cervical spine fracture found on computed tomography (CT), 40 were identified by history and physical examination alone.⁶ The clinical examination of cervical spine trauma has an overall sensitivity of 76.9%, specificity of 54.7%, positive predictive value of 15.5%, and negative predictive value of 95.7%.⁶ These values decreased in patients who presented with a low Glasgow Coma Score.⁶

In light of this data, prompt radiographic evaluation is critical to diagnose cervical spine injury. Plain film radiography (three-view cervical series) was the standard initial diagnostic test performed for suspected cervical trauma. Two clinical decision rules were developed for expeditious exclusion of cervical injury, selective radiography, and efficient healthcare utilization.⁷ First, the National Emergency X-Radiography Utilization Study Low-Risk Criteria (NLC) published in 1992 (Table 54.1) described five conditions that excluded the need for cervical spine radiography in trauma patients.⁸ This protocol demonstrated a sensitivity of 99.6% and specificity of 12.9% for cervical spine injury.⁹ Second, the Canadian C-spine rule (CCR) (Fig. 54.1) was developed to include high-risk and low-risk criteria and considered neck rotation as part of the evaluation criteria.¹⁰ Stiell et al.⁷ determined that in trauma patients who are alert and stable, the CCR has greater sensitivity and specificity to the NLC, thus resulting in greater radiographic selectivity.

Although plain radiographs were the standard initial diagnostic test performed for suspected cervical trauma, its use has come under considerable scrutiny. Muscle

spasm, edema, and neck pain following blunt trauma may technically limit the acquisition of flexion-extension films.¹¹ In addition, inadequate visualization of vital areas, such as the cervicothoracic junction, has restricted the use of plain films during the initial evaluation of cervical spine trauma. More importantly, the most significant reason for missed cervical spine injury is inadequate radiographic examination.¹²

Helical CT has therefore gained considerable momentum and greater acceptance to evaluate subaxial injury. The advantages of utilizing CT include the elimination of respiratory variations and the visualization of subtle findings that are otherwise masked on plain film.¹³ Also, shorter scanning time allows for prompt diagnosis with real-time interpretation of scans by trauma units.¹³ Helical CT provides image reconstruction, which is essential to visualize cervical alignment.¹³ After the incorporation of this imaging modality into standardized trauma protocols, the detection rate of cervical injury has improved from 54%, with plain film radiography, to nearly 100%.^{13,14}

Both CT and plain film radiography provide poor assessment of soft tissue structures including the intervertebral disk, spinal cord, and surrounding ligaments.¹⁵ In obtunded patients, with negative CT findings whose cervical spine cannot reliably be cleared clinically, MRI may be utilized to effectively assess ligamentous injury.¹⁶ The utilization of MRI to clear the cervical spine is under scrutiny as some authors believe a negative CT suffices for cervical spine clearance.¹⁷ Cervical clearance in the obtunded patient is controversial.¹⁸ Nevertheless, an MRI is indicated in patients with suspected facet subluxation or dislocation and in those with neurologic deficits.¹⁵ Hendey et al.¹⁹ evaluated the incidence of SCI without radiographic abnormality (SCIWORA), which was defined as SCI found on MRI with essentially normal initial plain film radiography in blunt cervical trauma. In SCIWORA patients,

Source: Stiell IG, Wells GA, Vandemheen KL, et al. The Canadian C-spine rule for radiography in alert and stable trauma patients. JAMA. 2001;286:1841-8.

central disc herniation, spinal stenosis, and cord edema or contusions were the most common MRI findings.¹⁹

CLASSIFICATION

Numerous cervical trauma classification methods²⁰⁻²² have been proposed in an attempt to incorporate the mechanism of injury, anatomic deformity, neurologic deficits, and the indications for surgical intervention. The lack of a widely accepted injury classification system has resulted in variability in the management of trauma patients.²³

Allen et al.²⁰ classified subaxial fractures into six categories based on the mechanism of failure. The probability of neurologic deficit was correlated with the type and severity of injury.²⁰ Although commonly utilized, this mechanistic classification scheme has never been validated among spine surgeons.²² Also, the Allen-Ferguson system fails to consider ligamentous stability, neurologic deficits, and is based on plain film radiography.^{22,23}

Subsequently, Anderson et al.²¹ developed the Cervical Spine Injury Severity Score (CSISS) based on both bony and ligamentous injuries.²¹ The CSISS divides the cervical spine into four columns and assigns a scoring system to describe the severity of injury.²¹ Surgical intervention was recommended for patients with a CSISS ≥ 7 .²¹ Although this system has demonstrated reliability, it does not offer insight into the treatment strategies for cervical injuries.²⁴

To address these limitations, Vaccaro et al. developed the Subaxial Injury Classification (SLIC) and Severity Score based on the validated Thoracolumbar Injury Classification and Severity Score system (Table 54.2).^{22,23} This classification scheme incorporates three independent predictors of outcomes: injury morphology, disko-ligamentous complex (DLC), and the neurologic status with subgroups within these categories.²² Each subgroup was provided a scoring system to facilitate decision-making for intervention.^{22,23} If the overall score is ≥ 5 , operative management is recommended. Although this comprehensive

	Points
Morphology	
No abnormality	0
Compression	1
Burst	2
Distraction	3
Rotation/translation	4
Disco-ligamentous Complex (DLC)	
Intact	0
Indeterminate (interspinous space widening, magnetic resonance imaging changes only)	1
Disrupted (disc space widening, perched facets or dislocation)	2
Neurological status	
Intact	0
Root injury	1
Complete cord injury	2
Incomplete cord injury	3
Continuous cord compression in setting of neurological deficit	+1

Source: Vaccaro AR, Hulbert RJ, Patel AA, et al. The subaxial cervical spine injury classification system: a novel approach to recognize the importance of morphology, neurology, and integrity of the disco-ligamentous complex. *Spine (Phila Pa 1976)*. 2007;32:2365-74.

system determines the need for surgery, it does not evaluate types of surgical intervention for various cervical injuries.²⁵ Therefore, Dvorak et al.²⁵ developed the first surgical treatment algorithm based on a cervical spine injury classification system.²⁵ The algorithm was designed within the framework of the SLIC scoring system and analyzed 26 articles with this classification.²⁵ The authors developed recommendations on the type of surgical intervention for various cervical injuries once the need for operative management was determined.²⁵

Stone et al.²⁶ evaluated the reliability of these three systems by classifying the radiographic images of 50 patients with subaxial cervical spine injuries and documented the need for surgical management.²⁶ The interobserver and intraobserver reliabilities for the CSISS and SLIC scoring systems were “excellent.”²⁶ The Allen-Ferguson system demonstrated “poor” interobserver but “excellent” intraobserver reliabilities.²⁶ With regard to surgical management decisions, the SLIC also demonstrated good interobserver and intraobserver reliabilities.²²

MANAGEMENT OF SELECTED INJURIES

The Spine Trauma Study Group (STSG) recently developed a standardized nomenclature to address the inconsistent terminology of cervical spinal injuries.²⁷ Eleven subaxial injury types and definitions were developed.²⁷ The overall interobserver and intraobserver agreements were 56.4% and 72.8%, respectively.²⁷ Lateral mass fracture, burst fracture, and flexion teardrop fracture were the most agreed upon injury types.²⁷ Therefore, this chapter discusses these selected injury types, and nonoperative and operative interventions based on the SLIC.

Burst Fracture

Vertebral body burst fracture (Figs. 54.2A and B) is associated with a loss of craniocaudal height and involvement of the posterior cortical margin.²⁷ Retropulsion of bone fragments into the spinal canal is often associated with this fracture.²⁷ The SLIC morphology score will be 1 or 2, DLC score of typically 0 (2 if the DLC is involved), and depending on the presence of neurologic injury, an additional 2, 3, or 4 points are added. Therefore, the extent of neurologic involvement underscores the decision for operative management.

Conservative treatment for stable burst fracture includes a halo vest for C3-C6 fractures while a cervico-thoracic brace should be utilized for C7 fractures. Cervical orthoses have demonstrated significant reduction in unrestricted head/base flexion and extension.²⁸ A cervical orthosis achieves transfer of loads through contact with the mandible, occiput, shoulders, and the upper back.²⁹ Appropriate orthosis selection is dependent on patient compliance, complications, and the immobilization capacity of each orthosis.²⁸

Typically, however, operative treatment is preferred for burst fractures. Koivikko et al.³⁰ compared patients with burst fractures treated with skull traction or halo vest with those treated with anterior decompression and stabilization. Surgically managed patients recovered faster with significantly less neurological deficits and kyphotic deformity at final follow-up.³⁰ The results of this study were consistent with other reports that anterior surgical decompression and fusion was superior to conservative management of burst fractures.^{25,30,31} In their algorithmic approach, Dvorak et al.²⁵ also recommended anterior cervical vertebrectomy with cage or strut graft and anterior cervical plating. The benefits of the anterior approach

include vertebral body resection, direct decompression of the neurologic structures, and stabilization of the injured anatomic structures.^{25,31-34}

Flexion Teardrop Fracture

Flexion teardrop fractures (Figs. 54.3A to D) are associated with a triangular, or quadrangular, bone fragment originating from the anteroinferior vertebral body.²⁷ By definition, concurrent cranial-caudal height loss must be present.²⁷ This injury is in contrast to an extension teardrop fracture found at C2 in the elderly, which is typically stable. Flexion teardrop fractures account for 8–15% of all cervical

fractures.³⁰ The SLIC morphology score will be 4, DLC may be 2, and up to 4 points may be added depending on neurologic manifestation. In general, these injuries require surgical management.

In the literature, one case series reports adequate stability of the cervical spine following only nonoperative management of cervical teardrop fractures.³⁵ The authors describe their closed reduction technique as follows: initial skull traction with halo fixation following 2–6 weeks of skull traction in the supine position.³⁵ Patients were treated with Minerva jackets following 6 weeks of skull traction.³⁵ Of the 10 patients managed with this technique,

only one required surgical fusion due to delayed instability.³⁵ Regardless, the general consensus supports surgical management for this injury due to the high rate of instability and increased risk of neurological injury.³¹ Toh et al.³¹ compared the halo vest and surgical management and established the superiority of decompression and fusion over conservative treatment. Similarly, Fisher et al.³⁶ determined that anterior cervical corpectomy with plating was safe and demonstrated superior outcomes to the halo vest for cervical flexion teardrop fractures.

Dvorak et al.²⁵ recommend a circumferential anterior and posterior open reduction fixation and fusion because the majority of these fractures are associated with significant posterior element failure, thus creating three-column instability. In contrast, Toh et al.³¹ favored an anterior decompression and fusion alone arguing that fixation and postoperative immobilization were enough to avoid a circumferential approach. To compare these techniques, Song and Lee³⁷ analyzed anterior versus circumferential internal fixation and fusion for subaxial cervical flexion injuries, and demonstrated no differences in complications, fusion rate, or neurologic outcomes. Because the majority of teardrop fractures are associated with DLC injury, a circumferential technique may be the best surgical approach for this fracture, especially if a significant posterior injury is found on MRI.²⁵

Facet Subluxation and Dislocation

Unilateral or bilateral facet subluxation and dislocation (Figs. 54.4A to E) result from translational or rotational injury. The deformity is characterized by malalignment of two adjacent vertebrae forming partial apposition of the facet articular surfaces.²⁷ Unilateral facet dislocation occurs when the inferior articular process of the cranial vertebrae has translated anterosuperiorly over the superior articular process of the caudal vertebra.²⁷ Bilateral facet dislocation is the disruption of both facet joints and is associated with comminution or fracture of the facet joint complex.²⁷ Unilateral facet dislocation is associated with <25% translation of the superior vertebral body on that of the inferior vertebral body, whereas bilateral dislocations typically demonstrate >50% translation.³⁸ Perched facets qualify as dislocation so long as no articular surface apposition is appreciated.²⁷

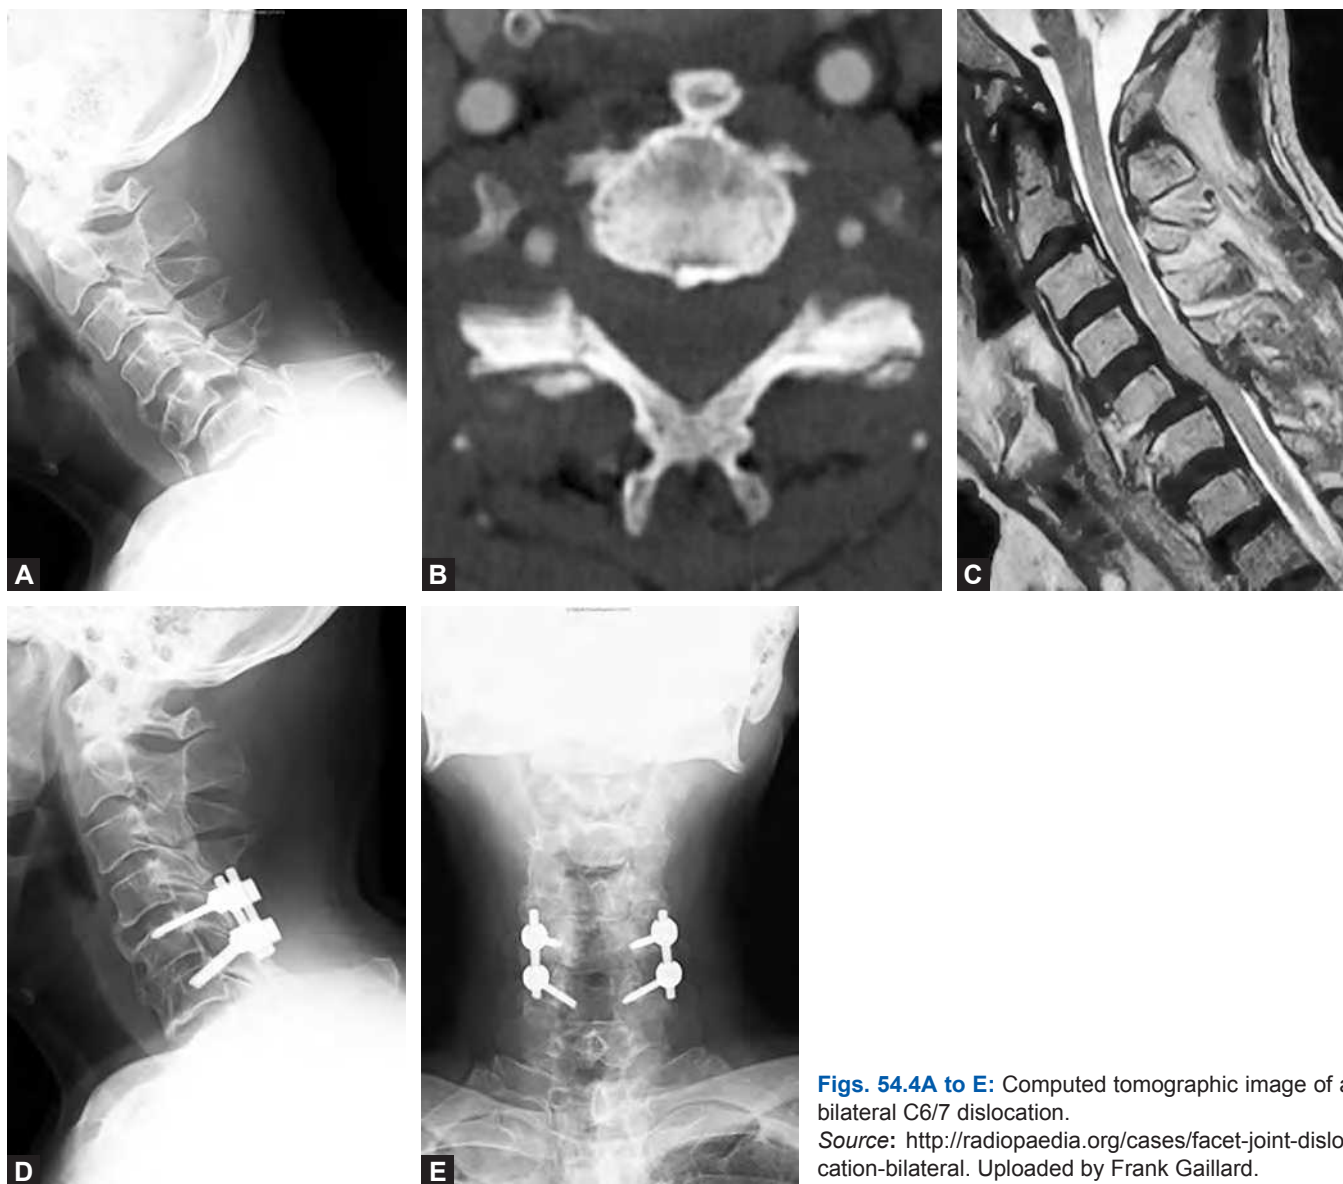

The SLIC morphology score will be 4, the DLC score will be 2, and the neurologic score will vary between 0 and 4 depending on complete and incomplete SCI. Facet dislocations represent the most unstable injuries from subaxial

cervical trauma.^{22,25} In most cases, surgical intervention is necessary to decompress neural structures and to restore stability to the vertebral column.

In these injuries, the intervertebral disc may herniate resulting in spinal stenosis. The timing of MRI is controversial but is typically dependent on the patient's neurologic condition.³⁹ A closed reduction should occur prior to an MRI if the patient presents with a complete SCI.³⁹ In other situations, closed reduction should only be attempted if the patient is awake and cooperative with serial neurologic examinations to monitor neurologic status during the procedure.^{39,40} Otherwise, if obtunded, an MRI should be obtained prior to any intervention.³⁹ Although closed traction reduction prior to an MRI of cervical facet dislocation in awake and alert patients with neural monitoring is acceptable, one case report in the literature by Wimberley et al.⁴⁰ reports acute quadriplegia immediately following this procedure. In such complications, the authors recommend prompt reversal of reduction (i.e. flexion of the cervical spine), SCI steroids, and an emergent MRI to assess neurologic compression.⁴⁰ An emergent surgical neural decompression is warranted if an anatomic compressive pathology is demonstrated on advanced imaging.⁴⁰

Following closed reduction, halo orthosis or continuous traction should be applied to maintain the reduction. Dvorak et al.⁴¹ compared 90 isolated unilateral fractures, subluxations, and dislocations treated surgically versus nonoperatively, and determined that the nonoperative cohort reported greater pain and disability particularly at longer follow-up. This report mirrors similar studies that have demonstrated superior outcomes with surgical intervention.^{34,42,43} In a radiographic series, Beyer et al.⁴⁴ reported that anatomic reduction was achieved in 60% of the operative group compared with 25% of those with an orthosis. In fact, during halo-thoracic immobilization, half of the patients lost reduction.⁴⁴ The burden of cervical instability and risk of neurologic compromise associated with these injuries provide considerable impetus for surgical intervention.

Operative management of traumatic facet subluxation and dislocation is highly variable and is dependent on the patient's neurologic status, presence of disc herniation, and bilateral facet involvement.⁴⁵ Nassr et al.⁴⁵ demonstrated poor agreement among surgeons in regard to interventional treatment options for these injuries. In the presence of a disc herniation, the evidence-based algorithm developed by Dvorak et al.²⁵ recommends anterior cervical discectomy followed by anterior closed reduction of the facet

Figs. 54.4A to E: Computed tomographic image of a bilateral C6/7 dislocation.

Source: <http://radiopaedia.org/cases/facet-joint-dislocation-bilateral>. Uploaded by Frank Gaillard.

subluxation/dislocation, and insertion of an interbody graft and plating. The anterior approach is favored to maximize decompression and disc fragment removal.³¹⁻³⁴ If an anterior reduction is unsuccessful, a circumferential open reduction, fixation, and fusion should be attempted.²⁵ The benefits of utilizing a circumferential approach in this situation, once again, include optimal neural decompression with an anterior approach and robust stabilization with posterior instrumentation.²⁵ Without a disc herniation, a posterior approach is utilized to treat ligamentous facet subluxation with the resection of the ligamentum flavum, and a lateral mass fixation and fusion.²⁵ Kwon et al.⁴⁶ demonstrated in a randomized control trial that

both anterior and posterior approaches were valid treatment options though anteriorly treated patients had less postoperative pain, better radiographic alignment, and a lower rate of wound infections.

Bilateral facet subluxations/dislocations are subject to greater degrees of kyphosis following posterior instrumented fusion.⁴⁷ A posterior fusion is utilized to treat bilateral facet injuries in order to provide greater biomechanical stability compared with an anterior approach.²⁵ Progressive disc space subsidence, which resists posterior fixation, is thought to contribute to the postoperative kyphosis.^{25,48} Therefore, some authors recommend early anterior fusion to address this complication.³⁴

Figs. 54.5A to D: Lateral mass fracture classification. (A) type 1; a separation fracture. (B) type 2; a comminution fracture. (C) type 3; a split type. (D) type 4; traumatic spondylolysis.

Lateral Mass Fracture

This fracture is an injury of any portion of the lateral mass complex including the articular process and the pedicle.²⁷ This definition also includes “floating lateral mass” created by ipsilateral fractures of the lamina and pedicle that result in articular process discontinuity with the native vertebrae.²⁷

The mechanism of injury will dictate the SLIC morphology score: one point for compression and four points for rotational or translational injury. The DLC score may be 2 depending on MRI findings. The extent of neurologic compromise can add up to four points. In addition to the SLIC, Kotani et al.⁴⁹ proposed another classification that divided lateral mass fractures into four subtypes: separation, comminution, split, and traumatic spondylolysis. The diagnosis of lateral mass fracture may require advanced imaging such as helical CT. Halliday et al.⁴² reported a 25% detection rate with the use of initial cervical plain film radiography.

In the literature, there is considerable variation regarding the management of these injuries. Nonoperative techniques include the application of a Miami J collar or the halo vest. Lee and Sung⁵⁰ described a case series of 39 patients with lateral mass fractures of which 15 were trialed with a rigid collar. The orthosis was successful in three patients while the remaining required delayed fusion to treat persistent pain and late instability.⁴⁹ Therefore, surgical intervention is likely necessary to provide stability in these injuries. Spector et al.⁵¹ found that unilateral facet fractures with >40% of the absolute height of the intact lateral mass or an absolute height >1 cm are at increased risk for failure of nonoperative treatment.

Kotani et al.⁴⁹ recommend a posterior approach with a cervical pedicle screw fixation for lateral mass fractures

only with minimal disc damage due to the risk of residual anterior translation of the repaired vertebra. Also, severely comminuted fractures with coronal plane malalignment may require two-level posterior fixation (Figs. 54.5A to D).⁴⁹ Single-level anterior arthrodesis of lateral mass fractures may result in failed reduction, cephalad vertebra translation, or malalignment due to short segment fusion.⁵⁰ In these cases, a revision posterior fusion may be required.⁵⁰

SUMMARY

Subaxial cervical spine injuries contribute to the majority of cervical fractures and dislocations. Prompt diagnosis is essential for immobilization and appropriate surgical intervention. Although a number of classifications have been proposed, the SLIC scoring system provides a holistic approach to each injury by characterizing the injury morphology, the disco-ligamentous complex, and the presence of neurological deficits. The subaxial cervical trauma nomenclature designed by the STSG defines 11 types of lower cervical spine injuries, thereby providing a standardized terminology. Although there is considerable variation regarding the management of subaxial injuries, evidence-based algorithms have been proposed to facilitate nonoperative and surgical decision-making.^{25,39}

Revision Anterior and Posterior Cervical Spine Surgery

Han Jo Kim, K Daniel Riew

Snapshot

» Evaluation

» Causes for Revision Surgery

INTRODUCTION

Revision cervical spine surgery can often be challenging from a technical and clinical perspective. From a technical standpoint, revision surgery requires careful dissection, and preoperative planning secondary to altered anatomy. In addition, revision cervical surgery can be complicated by a lack of bone stock, thereby requiring alternative methods of fixation. Clinically, these cases can be difficult from a diagnostician's perspective because of ambiguity of presentation. For example, a patient with a pseudarthrosis can present with pain that follows a radicular pattern. Such cases require a thorough diagnostic workup, preoperative planning, and execution. When performing revision procedures, the surgeon should do everything possible to ensure that it is the final revision for the operated levels.

EVALUATION

Patients in need of revision cervical spine surgery should all undergo a thorough history and physical examination. Special attention is turned toward changes in the pattern of symptomatology compared to a time point before the index operation, new neurologic deficits, and duration of symptoms. These aspects of the patient presentation can help distinguish complications related to the index operation (i.e. pseudarthrosis and persistent stenosis) versus those that are new (i.e. adjacent segment degeneration).

Radiographic evaluation is an integral part of this diagnostic workup. Standard radiographs of the cervical spine

should include anteroposterior, lateral, flexion, and extension radiographs as well as obliques. These X-rays can help in diagnosing pseudarthrosis, malalignment, and adjacent segment disease as well as evidence of hardware malposition/loosening or failure. If there is evidence of new-onset deformities in the sagittal or coronal planes, and revision surgery requires instrumentation into the upper thoracic spine, long cassette radiographs are helpful in order to assess sagittal balance.

A computed tomography (CT) scan is also performed as an adjunct to plain radiographs. First, it can further delineate the bony anatomy as well as identify subtle pseudarthroses that are not visible on plain radiographs. To diagnose a solid fusion on a CT, there should be bridging bone, not just at the graft-host surface, but also outside the confines of the graft or cage (Fig. 55.1). Second, it also helps to visualize the integrity and position of prior instrumentation. Third, it determines the amount of the bone stock left after the initial surgery. For example, after a patient has had a prior decompression of C2, the CT scan can help in determining the bone stock available for fixation options at that level or if fixation must be extended to levels distal and proximal in order to achieve adequate fixation. Finally, it can help to determine fusion levels. For example, if a patient requires a long fusion down to T2 but happens to have severe facet arthrosis at T2-T3 and an autofusion at T3-T4, only a CT would reveal these findings to the surgeon. Failure to appreciate such a finding would most likely result in poor postoperative outcomes.

Fig. 55.1: Computed tomography scan demonstrating bridging bone not only within the graft, but also outside (arrows) the confines of the graft.

Magnetic resonance imaging (MRI) is an essential tool in working up a patient with neurologic symptoms after prior cervical spine surgery. MRI is helpful for visualizing the integrity of the neural elements, soft tissues, and in some sequences, fusion status (i.e. T1 sequences). Contrast enhancement can also help in diagnosing recurrent lesions. The only difficulty of MRI in a patient undergoing revision cervical spine surgery is the artifact from previous instrumentation that can make the study difficult to interpret. In such conditions, CT myelography can be helpful.

Electrodiagnostic studies can also be helpful in some cases where the diagnosis might be difficult to obtain with conventional methods. Electromyogram or nerve conduction studies can help distinguish acute versus chronic radiculopathy in patients with residual foraminal stenosis. It may also help in diagnosing pathology unrelated to the cervical spine such as peripheral nerve entrapment syndromes or other conditions such as amyotrophic lateral sclerosis.

Lastly, if the diagnosis is still difficult to make with less invasive methods, a diagnostic nerve root injection can be very helpful in arriving at the correct diagnosis before undertaking a revision surgery. One example is the use of regional injections to the greater occipital nerve in helping to distinguish high cervical radiculopathy versus cervicogenic headaches from prior C1–C2 instrumentation causing irritation of the C2 dorsal root ganglion.

CAUSES FOR REVISION SURGERY

The causes for revision surgery in the cervical spine can be broken down into short-term and long-term etiologies.

Early etiologies include epidural hematomas or wound hematomas, radiculopathy from instrumentation malposition, incomplete decompression, or iatrogenic malalignment (i.e. overvigorous compression of posterior instrumentation to “dial in” cervical lordosis). Late etiologies include pseudarthrosis, late infections, postsurgical malalignment (i.e. cervical kyphosis), and adjacent segment degeneration.

Hematoma

Acute airway compromise from a retropharyngeal hematoma after anterior cervical spine surgery occurs in 0.2–1.9% of cases.^{1–6} Although it occurs uncommonly, the rapid onset and life-threatening possibility of an expanding hematoma can lead to significant patient morbidity and mortality. If a patient is demonstrating difficulty breathing, low pulse oximetry, and clinical signs of asphyxiation, immediate bedside hematoma evacuation by opening the wound is recommended. Patients who are clinically stable, however, can usually undergo controlled hematoma evacuation under general anesthesia. It is important for the surgeon to have a heightened suspicion for high-risk patients such as those who have been on antiplatelet medications, warfarin, or high doses of nonsteroidal anti-inflammatory medications. These patients should be closely watched in the acute postoperative setting.

Sources of bleeding can be active or more commonly from injured, bleeding muscle edges of the longus colli muscles or bony surfaces. It is our routine to inspect the edges of the longus colli before closure and to use bipolar electrocautery to stop any active bleeding as well as Surgicel and Surgiflo to coat the edges of the muscles before closure. In addition, bone wax is used for stopping bone bleeding, especially at the site where the caspar pins were placed. In situations where a corpectomy is performed and there is an abundant area of exposed bleeding bone, we address the bleeding during the surgical procedure with the combination of bone dust (which accumulates from our burr use during a decompression), a patty cottonoid, and some demineralized bone matrix soaked in thrombin. The combination of these and momentary pressure results in dry surgical field. Thus, irrigation to clean out the bone dust is used sparingly since it can aid in achieving hemostasis. In addition, punctate bleeding allows ingress of osteoprogenitor cells, so a completely dry field is not desirable.

For our anterior one-level procedures, this technique for achieving hemostasis has most commonly obviated the use of postoperative drains and has also allowed for one-level anterior cervical decompression and fusions

Fig. 55.2: Posterior cervical wound. Before commencing closure, a thrombin-soaked gelfoam is placed within the wound.

(ACDF) to be performed on an ambulatory basis. For multi-level procedures and corpectomies, however, we usually implement a drain overnight to allow for the evacuation of minor oozing. Although we rarely use bone morphogenetic protein 2 (rhBMP-2) in the anterior cervical spine, when we do implement rhBMP-2, we place steroids in the retropharyngeal space. We use Penrose drains for all anterior procedures. Penrose drains are removed the next day, and in the rare event of using a closed suction drain, they are removed when they have <20 cc in an 8-hour shift, typically at 8–16 hours postoperatively.⁷

During our posterior procedures, hemostasis is achieved with a similar combination of bipolar electrocautery, Surgicel and Surgiflo in addition to a gelfoam-soaked thrombin that is cut into a large rectangular shape and placed into the wound before closure (Fig. 55.2). This stops the muscles from bleeding after the closure. One should not place gelfoam or an abundance of hemostatic agents on top of an exposed cord (e.g. after a laminectomy) as these will expand and can result in cord compression. We also place a drain below the hemostatic agent so that a hematoma does not cause cord compression. This method for minimizing blood loss and achieving hemostasis has been successful, and we have seen on average a 100-ml decrease in drain outputs in our posterior cervical cases.⁸ Since we routinely remove the drains once the output is <30 cc/8-hour shift for two consecutive shifts, we have been able to reliably remove drains on the first postoperative day and, overall, decrease the length of stay.

Regardless of the adjunctive product used for achieving hemostasis, meticulous dissection and attention to having a dry surgical field during the approach is an

essential aspect of preventing postoperative hematoma formation in the anterior or posterior cervical spine.

Radiculopathy

Little is reported on the incidence of postoperative radiculopathy. When it occurs, various etiologies from hardware malposition, incomplete decompression with residual stenosis, iatrogenic foraminal stenosis from excessive lordosis, and nerve root irritation are all possibilities to consider. The challenge of managing the patient with persistent pain in the immediate postoperative period lies in the inability to obtain adequate imaging studies at the level that was addressed at the index operation due to metal artifact. Therefore, CT myelogram is the study of choice to examine residual stenosis or remaining osteophytes that can be causing the symptoms. In addition, it can provide sufficient detail of the bony anatomy in order to rule out malposition of the instrumentation. Electrodiagnostic studies can be useful for determining the true etiology of neurologic deficits. This is especially valuable when imaging studies show no evidence of residual stenosis, but the patient has worsened or demonstrated persistent neurologic symptoms. In this situation, the nerve conduction studies can aid in diagnosing alternative explanations for the neurologic findings such as transient ulnar neuropathy or brachial plexopathy from positioning. Nerve conduction studies are useful after the 6- to 12-week time point. Nerve root injections can also be useful as a diagnostic and therapeutic maneuver when postoperative neuroforaminal stenosis is observed.

In posterior procedures, lateral mass screw placement that is too ventral, or a pedicle screw that is not optimally positioned, can result in radiculopathy. In addition, mild foraminal stenosis that is present preoperatively can worsen with excess cervical lordosis built in during surgery. With anterior procedures, foraminal stenosis can occur from an incomplete foraminal decompression or from oversized footprints of some arthroplasty implants that are placed too posteriorly. In either situation, if the cause of the radiculopathy in the acute postoperative period can be localized with a high degree of certainty, revision surgery is recommended in order to rectify the situation if conservative measures such as nerve root injections and pain medication fail.

Adjacent Segment Degeneration

After Hilibrand et al. reported the incidence of adjacent segment pathology (ASP) in the cervical spine to be approximately 2.9% annually and 25% over a 10-year period,

there has been continued controversy on whether ASP is truly a result of altered biomechanics from a fusion or progression of spondylosis in patients who have already demonstrated a propensity toward degenerative disease of the cervical spine.^{1,2,3,9,10} Biomechanical studies have shown altered adjacent disc pressures and motion in response to fusion at adjacent levels, providing objective rationale for the concept of ASP.¹⁰ Clinically, patients with Klippel-Feil syndrome demonstrate areas of degeneration localized most commonly to disc level, directly adjacent to the areas that are congenitally fused.¹² However, large studies on these patients to determine an annual incidence have not been performed, and many patients develop the need for surgery in their 40s, which is much later than what one would expect from degeneration caused primarily by adjacent fused segments.

While the occurrence of ASP may be inevitable, certain techniques can help in minimizing injury to the adjacent level during the index operation. One technique we implement is the use of a hemostat to localize our level. Instead of using a spinal needle to puncture the disk, we use the hemostat to clamp the fibers of the anterior longitudinal ligament or the longus colli muscle corresponding to the level. This prevents the possibility of inadvertently injuring the adjacent disc space. Another technique we use is trying to use the smallest size plate possible (<5 mm within the adjacent levels) in order to prevent adjacent-level ossification development (ALOD).¹³ This is held in position with fixed screws proximally and variable angled screws distally so that when the graft settles, the position of the plate from the adjacent disc level proximally is not shortened. Cranial adjacent levels have shown a higher propensity toward developing ALOD than caudal levels.

If a revision surgery is needed, the approach is dictated by the difficulty of the anterior versus posterior revision approach. A revision anterior approach is usually not difficult and often is a less morbid procedure for the patient. Usually, before the revision surgery, an otolaryngology consult is performed to ensure bilaterally functioning vocal cords. If there is a unilateral palsy, we perform the approach on the ipsilateral side.¹⁴ If bilateral vocal cords are functioning, an approach can be performed on either side. If for some reason an otolaryngology consult cannot be performed, we perform the surgery on the same side that the prior surgery was performed. If the previous approach was a high cervical one, and the contralateral side is to be approached, then the ears, nose, and throat evaluation needs to assess the integrity of the superior laryngeal

nerve. The superior laryngeal nerve has an internal branch that provides sensation to the posterior larynx. Because it is often dually innervated, damage to one side can be asymptomatic. However, damage bilaterally will result in aspiration from lack of sensation. If the external branch is injured, the loss of constrictor and cricothyroid muscles will result in the inability to scream or sing high notes.

The most common levels seen that develop degenerative disease and undergo ACDF are at the C5–C6 and C6–C7 levels. Therefore, revision surgery for adjacent segment degeneration often involves addressing pathology at C7–T1 or C4–C5. Although the C4–C5 disc space is easily reached with the anterior approach, C7–T1 may be more difficult. For cases like this, we localize our incision to favor the more distal level since it is easier to move proximally than distally. The C7–T1 level can be addressed in the vast majority of cases with an anterior approach as well as the T1–T2 level in some cases. Preoperative imaging can help predict the feasibility of this approach. If a straight line from the skin to the top of the manubrium lies just at or below the posterior aspect of the disc space to be decompressed, then the level can be reached (Figs. 55.3A to D). Sometimes this is only possible by doing a partial corpectomy of the cranial vertebra. Therefore, C8 or T1 radiculopathy does not necessarily portend itself to a posterior approach for addressing the pathology.¹⁵

Pseudarthrosis

Pseudarthrosis can be another reason for revision surgery in the cervical spine. In our experience, pseudarthrosis is the most common reason for recurrence of symptoms after surgery. Usually, it is diagnosed when patients have recurrent symptoms in addition to neck pain with radiographic evidence of failed fusion.^{16,17} This may be evident on plain radiographs by a radiolucent line across the level, loosened implants, and/or graft displacement. In more subtle cases, flexion/extension radiographs can demonstrate motion between the corresponding spinous processes, indicating motion and a likely pseudarthrosis. It is critical that flexion–extension radiographs be adequate. We explain to the patient and the radiology technician that we are looking for maximal flexion and extension views to the limits of the patient's ability. When assessing the adequacy, there must be at least 4 mm of motion at the tips of the spinous processes on one or more unoperated segments (Figs. 55.4A and B). On adequate radiographs,

Figs. 55.3A to D: A patient with T1 radiculopathy. (A) On standing X-rays, a straight line from the manubrium intersects the T1 vertebral body and just skims the posterior superior end plate of T2. This allowed for decompression of the C7–T1 disc space as well as T1–T2 disc space. (B and C) Postoperative X-rays of the surgery. (D) A hemicorporectomy was performed to facilitate decompression for the left-sided symptoms. Also, additional grafts were used in the disc space at the two levels to improve stability and fusion surface area (arrows). Adequate motion in the non-fused segments denote an appropriate flexion/extension image to assess for Pseudarthrosis at the fused segments.

Figs. 55.4A and B: Dynamic flexion–extension radiographs are shown. In order for the dynamic radiographs to be sufficient for diagnosing a pseudarthrosis, at least 4 mm of motion (measured from the spinous processes) should be seen in adjacent unfused levels (white arrows) while the levels that are fused show <1 mm of motion (black arrows) at 150% magnification.

magnified at least 150%, the interspinous process motion should be <1 mm to diagnose a fusion. If for any reason the dynamic views are indeterminate, a CT should be obtained. We have found that the most reliable criterion for a solid fusion is the presence of bone outside the graft within the uncinat process placed by the surgeon. This is especially true in cases where a polyetheretherketone spacer is utilized. Polyetheretherketone often gives the appearance of a solid fusion, especially when it is filled with granular materials. This is why it is imperative to obtain dynamic views and to assess for extra-graft bone formation.

Although rhBMP-2 is rarely used in the anterior spine, we on rare occasions use it for multilevel anterior procedures. Many of the side effects from rhBMP-2 use in the anterior cervical spine seem to be dose related, and we have not seen any of these complications associated with its use at doses we implement, usually 0.2–0.33 mg/level.⁷ Patients are cautioned that the Food and Drug Administration has strongly condemned the use of BMP-2 in the cervical spine as it has caused death, airway compromise due to massive edema, osteolysis, and other complications. New data also suggests the possibility of BMP-2 in high doses being associated with an increased risk of cancers. Other studies have demonstrated increased rates of reoperation and other complications associated with its use. We have not experienced such complications, perhaps due to our low dose and the fact that we place 10–20 mg of Depo-Medrol in the wound before closure, along with 250–500 mg of vancomycin powder. In addition, we put the BMP-2 on demineralized bone matrix instead of the collagen sponge, as it binds well and releases more slowly. With such techniques, our fusion rates for even four- or five-level anterior-only operations have been excellent. The total dose we use in the anterior spine is never more than an XX-Small (1.05 mg). It is imperative to explain the risk-benefit ratio to patients who will be receiving BMP and to have them sign a separate written consent.

The treatment for pseudarthrosis depends on the biomechanics of the construct, location of instrumentation, integrity of remaining bone, patient comorbidities, and patient symptomatology. In considering the biomechanics of the construct, we examine the presence or absence of instrumentation either anteriorly or posteriorly. For example, if a patient had undergone a prior ACDF without instrumentation and developed a pseudarthrosis, we would most likely proceed anteriorly for the revision surgery. This is contrast to pseudarthrosis in a patient who may have undergone a one-level ACDF with instrumentation who

is also a smoker and diabetic. In these patients, we would address the pseudarthrosis with a posterior instrumentation and fusion. In addition, if there was instrumentation that was dislodged or a graft that was displaced, we would be more inclined to pursue an approach in order to address the displaced elements and, depending on the number of levels, perform an anterior or posterior approach as an adjunct. If there is poor remaining bone stock, we would be most inclined to lengthen our construct and/or to perform a combined anterior and posterior approach for addressing pseudarthrosis. Lastly, if a patient presents with radiculopathy localized to the level of the pseudarthrosis, a posterior approach is used in addition to a foraminotomy. This approach will usually lead to a fusion of the anterior cervical spine due to the added rigidity of the posterior instrumentation resulting in a circumferential fusion.

Malalignment

Iatrogenic malalignment can occur due to a variety of reasons and can also manifest as either excessive cervical lordosis or kyphosis. Both patients will present differently. Excessive cervical lordosis can result in iatrogenic foraminal stenosis, necessitating return to the operating room in the acute postoperative period. In this situation, a review of the preoperative films for hypertrophic superior adjacent processes should be utilized since instrumentation artifact will make it difficult to evaluate the foramen. A return to the operative room should involve a posterior foraminotomy in addition to less rigorous compression for generating cervical lordosis.

Malalignment from iatrogenic cervical kyphosis will usually present later with failure at the bone-instrumentation interface at the distal levels of the fusion or in the subacute postoperative period, with patients having difficulty maintaining forward gaze. One additional cause of iatrogenic cervical kyphosis is a kyphosis that develops over time such as that seen in postlaminectomy kyphosis in the uninstrumented spine.

Patients who have difficulty maintaining forward gaze due to their head position usually have had fusions extended to the occiput. This can usually be avoided by having patients take a preoperative radiograph in the position they find most comfortable and then using intraoperative radiographs to match the alignment. This becomes more difficult for cases of chin-on-chest deformities where the deformity does not allow for patients to lift their head to obtain such a radiograph. In this case, limitations on how much extension to aim for during corrective osteotomies

Figs. 55.5A and B: A patient who had an anteroposterior fusion from the occiput to C7 (A), who developed distal junctional kyphosis, was successfully revised to T3 (B) with maintenance of her alignment at 4-year follow-up.

should take into consideration the importance of maintaining some flexion so patients can see their feet during ambulation in addition to ensuring there is mild laxity to the anterior soft tissue structures such as the strap muscles as well as the esophagus in order to allow for swallowing. Excessive tension by overcorrection can result in an inability to swallow, which will necessitate revision surgery or the use of a percutaneous endogastric feeding tube until the esophagus can be retrained in its new position.

Distal junction kyphosis can be seen in cases where the proximal lever arm created by the fusion mass lies too anterior to the trunk, resulting in excessive stress at the bone-screw interface at the distal levels (Fig. 55.5A). Anecdotally, we have had less distal problems when the construct is made in a way that a plumbline from the basion is anterior to the manubrium after the corrective osteotomies are performed (Fig. 55.5B).

Postlaminectomy kyphosis occurs in up to 30–40% of cases for patients with neutral alignment.^{18,19} Careful posterior dissection being mindful of the laminectomy defect is the most tedious portion of the approach. Once the lateral masses are exposed, instrumentation is implanted. For cases where there is excessive scar posteriorly over the thecal sac, care must be taken not to cause buckling of the scar when generating a physiologic amount of cervical lordosis. Excessive scar tissue can be excised with a No. 15 blade once the interval between the dura and scar is identified bluntly with a cervical Cobb elevator (Fig. 55.6). It is also important to examine the preoperative MRI and/

Fig. 55.6: Sharp and blunt dissection is used to “peel” the scar off the dura. As mentioned in the text, the Cobb is held in a way that half of it lies on the bony facet and determines the depth of our sharp dissection. Once a plane is delineated, the majority of the scar can be peeled off slowly.

or CT to determine how dorsal the dural sac protrudes past the bony lamina of the segments above and below the laminectomy defect. The spinous processes are exposed subperiosteally and then continued to the laminar defect, stopping when the dissection is 5–10 mm above the dura (based on preoperative imaging studies). After exposing the cord, care is taken to avoid dropping anything on top of it, especially while instrumenting.

Regardless of the type of malalignment, revision surgery should involve an evaluation of the flexibility of the defor-

mity. Rigid deformities will necessitate osteotomies, while flexible deformities do not.²⁰ Usually, plain radiographs in the upright and supine positions can be an indication of the flexibility of a deformity. For revision surgery where prior instrumentation was performed, a CT scan can help in identifying fused and nonfused segments for adequate preoperative planning. It has been our experience that an anteroposterior combined approach, when possible, results in less blood loss and less operative time while providing similar corrections to a pedicle subtraction osteotomy. The caveat to this is that in severe deformities, an anterior approach is not feasible and in such cases, a pedicle subtraction osteotomy is the only option. Otherwise, an anterior osteotomy combined with posterior column osteotomies (Smith-Petersen or Ponte type) should be able to provide adequate correction in most cases.

KEY POINTS

- Early etiologies for revision surgery include epidural hematomas or wound hematomas, radiculopathy from instrumentation malposition, incomplete decompression, or iatrogenic malalignment. Late etiologies include pseudarthrosis, late infections, postsurgical malalignment (i.e. cervical kyphosis), and adjacent segment degeneration.
- In our experience, pseudarthrosis is the most common cause for revision surgery. It can be approached via an anterior or posterior approach based on the biomechanics of the construct, location of instrumentation, integrity of remaining bone, patient comorbidities, and patient symptomatology.
- The ALOD after ACDF can be minimized by keeping the plate at least 5 mm from the adjacent cranial disc space.
- In addressing cervical deformity cases, it is our recommendation to bring the basion plumbline as close as possible to the manubrium to prevent distal junction kyphosis.
- In performing corrective osteotomies for sagittal plane deformities, some flexion should be maintained so patients can see their feet during ambulation in addition to ensuring there is mild laxity to the anterior soft tissue structures, such as the strap muscles and esophagus, in order to allow for swallowing.

INTRODUCTION

Acute traumatic spinal cord injury (SCI) is a devastating condition oftentimes accompanied by a cascade of complications including hemodynamic instability, pulmonary dysfunction and metabolic derangements. The acute management of SCI is multifaceted and is crucial to long-term neurologic prognosis. Initial assessment should focus on early stabilization of the cervical and thoracolumbar spines to prevent repeated injury, followed by transportation to an appropriate acute care setting for diagnosis and treatment. Respiratory and hemodynamic status should be rapidly assessed and corrected to mitigate ongoing injury to the spinal cord ischemic penumbra. Spinal instability and ongoing compression should be addressed through early closed reduction or surgical decompression, and the judicious use of corticosteroids can be considered for neuroprotection in patients presenting within 8 hours of injury.

In addition to established guidelines, this chapter will also touch on novel treatments on the cusp of human translation. Minocycline, riluzole, and Cethrin® target various aspects of the secondary injury cascade and hold promise as neuroprotection agents. Stem cell transplantation allows for replacement of lost cells in addition to protection of surviving axons, and has shown promise

in models of both acute and chronic SCI. Lastly, therapies including cerebrospinal fluid (CSF) drainage and therapeutic hypothermia have also been shown to be beneficial in animal models and to be safe in human phase I/II trials, and thus constitute an exciting area of investigation with potential for incorporation into future treatment algorithms.

EPIDEMIOLOGY AND COSTS

The worldwide annual incidence of acute traumatic SCI is 15–40 cases per million, which carries significant socioeconomic impact.^{1,2} In the United States, the prevalence of SCI is 270,000 with 12,000 new cases occurring annually.^{3–5} Common mechanisms of injury include motor vehicle collisions (39.2%), falls (28.3%), violence (14.6%), and sporting accidents (8.2%).⁴ The majority of acute SCI patients are males (80.6%), and the average age of injury is 40.6 years, with a peak in young adulthood due to violence and accidents, and a second smaller peak in the elderly due to increased falls.⁴

Approximately 60–75% of acute SCI occurs in the cervical spine, 15% in the thoracic spine and 10% in the lumbosacral spine.^{1,6} Despite advancements in the acute management and supportive care of SCI, 15–20% of patients die prior to arriving in hospital.⁷ In the surviving

population, prognosis is particularly poor in high tetraplegia and ventilator-dependent patients, who face a 1-year mortality of 8.2% and a life expectancy of only 10–15 years post injury—septicemia and pneumonia are the leading causes of death in these patients.^{3,4,8} The societal and individual costs of SCI are extensive. Depending on the level and severity of injury, expenditure associated with acute care, rehabilitation, and lost productivity can exceed \$1 million in the first year after injury and up to \$25 million in a lifetime.^{4,8}

PROGNOSIS

The all-cases cumulative survival of acute SCI is 94% at 1 year and 86% at 10 years.⁹ Mortality is predicted by multiple factors, including increasing age, higher level of neurologic injury, and concomitant traumatic brain injury (TBI) or severe systemic injury.^{10,11} Complete SCI patients experience mortality rates that are three times higher compared to their incomplete SCI counterparts.⁹ In an Australian study, at 10 years post injury, 22% of C1–C4 SCI patients had died compared to 13% of C5–C8 patients and 7% of T1–S5 patients.⁹ Geriatric SCI patients > 70 years of age suffered higher in-hospital mortality of 27.7% compared to 3.2% for adults younger than 70.¹²

The neurologic prognosis following SCI is dependent on the level of injury and American Spinal Injury Association Impairment Scale (AIS) grade on presentation, with the extent of anticipated recovery diminishing as the injury severity increases.¹¹ On average, at 1-year follow-up, AIS A patients will improve 12 points in the ASIA Motor Score (AMS) compared to 28 points for AIS B patients, and 43 points for AIS C patients. At 1 year, approximately 10–15% of AIS A patients will convert to incomplete status, with only 2% improving to AIS D. One-third of AIS B patients will improve to AIS C, and one fourth to AIS D or E. Seventy percent of AIS C patients will improve to AIS D or E. The motor gains are more limited in AIS D patients, with only 4% converting to AIS E, largely due to the ceiling effect. There is a consensus across literature that patients with complete thoracic SCI have a reduced potential for neurologic recovery compared to their cervical SCI counterparts due to (1) increased force required for thoracic spine disruption, likely resulting in increased neural tissue damage, and (2) inability to detect neurologic change in T2–T12 levels, thus neglecting any neurologic improvement that may occur. This difference was not observed in incomplete SCI.

PATHOPHYSIOLOGY

Acute SCI consists of the initial traumatic event known as the primary injury, followed by a prolonged and progressive cascade of events constituting the secondary injury. At a macroscopic level, primary injury results from a compressive force applied to the spinal cord arising from (1) bone, disc or ligamentous material extruding into the spinal canal, (2) extradural hematoma formation, or (3) dynamic instability of the spinal column.^{13,14} Diffuse axonal injury, petechial hemorrhages, and vascular shearing can also result from distractive forces. Within seconds, the initial spinal cord trauma initiates a signaling cascade of downstream events collectively known as the secondary injury. The neuroinflammation, free radical formation, glutamine-mediated excitotoxicity, and lipid peroxidation lead to gradual expansion of the initial lesion in a rostrocaudal direction from the injury epicenter.⁸ As a result, gray matter loss and white matter degeneration persist for up to several weeks, contributing to neurologic decline in a prolonged and progressive fashion. In addition, reactive astrocytes interact with microglia, undergo morphological changes, and increase synthesis of glial fibrillary acidic protein.¹⁵ This process is the main component of astrogliosis, leading to the formation of a hostile environment not conducive to neural regeneration. While injury prevention and early closed or open reduction aim to mitigate primary injury, the majority of neuroprotective agents target stages of the secondary injury cascade to attenuate the neuroinflammatory responses.

INITIAL ASSESSMENT

Assessment and management of acute SCI begins at the scene. Approximately 20% of cervical SCI involve multiple noncontinuous vertebral levels, and 35% are associated with TBI.¹⁶ Therefore, assessment of multisystematic trauma, level of consciousness, spinal pain or tenderness, and focal neurologic deficits is important in the context of SCI. Patients at risk for spinal injury should be immobilized with a combination of rigid cervical collar and supportive blocks on a backboard, in addition to log-roll techniques to secure the entire spine.¹⁷ Following initial assessment and resuscitation, the patient should be transported to the nearest capable definitive medical care facility, and to a SCI treatment facility if possible.¹⁸

In alert and cooperative patients, assessment of neurologic deficits, spinal step deformities, and local tenderness provides insight into the diagnosis of SCI. Neurologic

Table 56.1: ASIA impairment severity (AIS as modified from Frankel) grade classification.¹⁹

Class	Description
A	<i>Complete:</i> no sensory or motor function is preserved in sacral segments S4 and S5
B	<i>Incomplete:</i> sensory, but not motor, function is preserved below the neurologic level and extends through sacral segments S4 and S5
C	<i>Incomplete:</i> motor and sensory function is preserved below the neurologic level. Most key muscles below the neurologic level have a muscle grade of <3
D	<i>Incomplete:</i> motor and sensory function is preserved below the neurologic level. Most key muscles below the neurologic level have a muscle grade of ≥3
E	<i>Normal:</i> sensory and motor functions are normal

assessment should proceed in accordance with the ASIA International Standards for Neurological Classification of Spinal Cord Injury (ISNCSCI).¹⁹ Originally developed in 1982, the ISNCSCI consists of three main components and is the most widely accepted classification system in clinical use.²⁰ The AMS is based on the power of 10 myotomes bilaterally, rated between 0 (no movement) and 5 (full power). The ASIA Sensory Score consists of pinprick and light touch sensation based on 28 dermatomes bilaterally, ranging from 0 (no sensation) to 2 (normal sensation). Lastly, the neurological level of injury identifies the spinal level of at least three-fifths power and sensory function bilaterally. Outlined in Table 56.1, the AIS classification sorts SCI into five categories from AIS A (complete injury, no motor or sensory function) to AIS E (normal examination). In addition to the initial assessment, SCI patients should be examined serially throughout hospitalization, specifically at 72 hours post injury for an accurate baseline examination following resolution of potential confounding spinal shock, and at 1 month post injury for prognostication of neurologic recovery.²¹

RADIOGRAPHIC ASSESSMENT

Radiographic diagnosis of cervical SCI begins with two assessment tools, developed through multicenter prospective observational studies, to stratify risk for cervical spinal injury. The National Emergency X-Radiography Utilization Study (NEXUS) assessed five factors in the prediction of cervical spine injury and concluded that patients who have no neurologic deficits, normal alertness, no intoxication, no midline cervical tenderness, and no painful distracting injury have a 99.8% negative predictive value for

cervical spine injury.²² The Canadian C-Spine Rule (CCR) provides an alternative assessment algorithm based on patient age, injury mechanism, extremity paresthesia, and cervical range of motion.²³ Retrospective analyses comparing the validity of these two scores found the CCR to be more sensitive and specific than the NEXUS low-risk criteria (NLR) for detection of cervical spine injury,^{24,25} although both scores are widely used in the Emergency Department. Low-risk patients determined by the CCR or NLR should be cleared of cervical immobilization without radiographic evaluation.¹⁸

In alert and symptomatic patients with spinal tenderness, neck pain, or neurologic deficits, further investigation with computed tomography (CT) or high-quality three-view cervical spine radiographs (CSR) should be used for injury assessment. Computed tomography is the imaging modality of choice, as it is very sensitive for defining bony fractures, spinal deformities, and canal patency. In the literature, CT has demonstrated superiority in cervical spine fracture detection, approaching 100% sensitivity compared to 36–64% sensitivity with CSR.²⁶ When CTs are not available, high-quality three-view CSR covering the entire spine from the craniocervical junction to the C7–T1 junction can be used. Abnormal spinal alignment or angulation, widening of joint and disc spaces, and presence of soft tissue swelling all contribute to possible diagnosis of spinal injury.

Patients with CT or X-ray evidence of spinal injury should undergo magnetic resonance imaging (MRI) to (1) identify pattern and anatomic level of cord injury for prognostication, and (2) identify soft tissue injury, ligamentous disruption, intervertebral disc herniation, or vertebral artery injury that will affect overall management. MRI is also valuable and recommended for elderly patients with comorbid spinal conditions like ankylosis, ankylosing spondylitis and diffuse idiopathic skeletal hyperostosis (DISH). T2 sagittal views are the most helpful for the detection of cord injury.²⁷ In one prospective study, the presence of hemorrhage, edema, cord swelling, increased spinal cord compression and canal compromise, as well as longer rostrocaudal lesion length, was associated with worse clinical prognosis.²⁸ MRI or dynamic flexion–extension cervical spine X-rays can also be provided as options for symptomatic patients with a normal CT, although their roles in the management of those patients are less evident.²⁶

All obtunded patients should undergo high-quality CT as the first imaging modality of choice, since no reliable clinical examination is available. In the case of a normal

CT, multiple prospective studies and retrospective reviews have attempted to appraise the role and value of MRIs in detecting what CTs have missed. Proponents advocate for its use in evaluating ligamentous injury; in one large meta-analysis, MRI detected abnormality in 12% of CT-negative patients, leading to altered management (surgical stabilization or immobilization) in 6%.²⁹ These meta-analyses are balanced with other data that reveal no added benefit in obtaining MRI. To reconcile conflicting class II/III evidence, the 2013 American Association of Neurological Surgeons (AANS) and Congress of Neurological Surgeons (CNS) guidelines advocate the following strategies for obtunded patients with normal CT: (1) continue cervical immobilization until asymptomatic, (2) discontinue cervical immobilization following a normal MRI study obtained within 48 hours of injury, or (3) discontinue immobilization at the discretion of the treating physician.²⁶ Routine use of dynamic flexion–extension X-rays is of marginal benefit and is not recommended.²⁶

GENERAL MEDICAL CARE

Progressive secondary injury follows the initial insult and is aggravated by local hypoxia and systemic hypotension. Demonstrated in animal and human studies, early identification and management of systemic hypoxia, pulmonary dysfunction, and cardiovascular instability plays a large role in mitigating secondary injury and improving neurologic outcome.

As per Advanced Trauma Life Support protocol, the primary survey of trauma patients includes assessment of airway, breathing, and circulation. Respiratory distress, tachypnea, desaturation, or a decrease in forced vital capacity below 15 mL/kg should be addressed.³⁰ Adequate oxygenation and mechanical ventilation is especially crucial for patients with high SCI above C5 due to loss of both intercostal and diaphragmatic innervation. In addition, patients with injuries above T6 are at risk of neurogenic shock from interruption of sympathetic pathways, leading to unopposed vagal stimulation and decreased systemic vascular resistance. These patients often demonstrate hypotension refractory to fluid resuscitation, relative bradycardia, and hyperemic warm skin. Approximately 25% of cervical SCI patients experience hypotension (systolic blood pressure <90 mm Hg) with relative bradycardia (heart rate < 90 bpm) acutely after injury, and patients with complete SCI are 5.5 times more likely to develop refractory hypotension compared to those with incomplete SCI.³¹

To support spinal cord perfusion pressure and to avoid ischemia, a mean arterial pressure (MAP) between 85 and 90 mm Hg should be maintained for the first 7 days following injury.³² Concomitant sources of hemorrhage and hypovolemia should be corrected, and judicious use of isotonic crystalloid fluids is the first-line therapy for hypotension. For neurogenic shock unresponsive to fluids, vasopressor agents should be considered to prevent iatrogenic pulmonary edema, congestive heart failure, and hyponatremia secondary to fluid overload. To address both peripheral vasodilation and bradycardia, an agent with both α - and β -adrenergic activity such as dopamine or norepinephrine is desirable.³³ Phenylephrine should be avoided due to its exclusive α -receptor activity and propensity to exacerbate reflexive bradycardia through peripheral vasoconstriction. Atropine, or in refractory cases, pacemaker placement, can be used to correct bradycardia.

For patients with SCI above T6, temperature regulation also presents as a challenge due to lack of effective afferent pathways from skin receptors and the inability to regulate vasoconstriction, vasodilation, and sweating in the insensate portion of the body.³⁴ Partial poikilothermia develops, leading to drastic shifts in core body temperature in concordance with ambient temperature.³² Metabolic derangements, including post-traumatic hypokalemia, may occur in up to 54% of SCI patients, hypothesized to be a result of increased plasma epinephrine release during periods of hypovolemia and hypotension.³⁵ Pulmonary dysfunction, gastrointestinal ileus, urinary retention, deep vein thrombosis, autonomic dysreflexia, and decubitus ulcers are also common in SCI patients and should be prevented or treated early in the disease course.

Even in situations of initial hemodynamic stability, patients with acute cervical SCI are at risk for life-threatening episodes of hypotension, bradycardia and cardiac irregularities, especially over the first week.³⁶ Based on level III evidence, the AANS/CNS guidelines recommend admission into an intensive care unit for the first 7–14 days, during which patients are particularly susceptible to complications.³² In the United States since 2005, the median length of stay in an intensive setting following SCI was 11 days, but increased for patients with neurologically complete injuries.³⁷ Adequate early medical care in an appropriate setting is crucial in the management of SCI. Some important guidelines and the accompanying level of evidence are presented in Table 56.2.

Table 56.2: Guidelines for the acute management of spinal cord injury.

Parameter	Guidelines	Level of evidence
Early immobilization	Spinal immobilization for all trauma patients with a combination of rigid cervical collar, supportive blocks on a backboard with straps and log-roll technique	III
Hemodynamics	Correction of hypotension (sBP < 90 mm Hg)	III
	Maintenance of MAP between 85 and 90 mm Hg for the first 7 days following acute SCI	III
Care setting and monitoring	Management of patients with acute cervical SCI in an intensive care unit or similar monitored setting	III
	Use of cardiac, hemodynamic, and respiratory monitoring devices to detect cardiovascular dysfunction and respiratory insufficiency	III
Thromboembolism prophylaxis	Venous thromboembolism prophylaxis including the use of low molecular weight heparin, pneumatic compression boots and rotating beds	II

SURGICAL MANAGEMENT OF SCI

A select group of SCI patients would benefit from surgical decompression, with goals to (1) restore biomechanical stability to the spinal column and (2) optimize neurological outcomes by decompressing the spinal cord and neural elements.³⁸ A combination of factors should be taken into consideration when making the decision to operate, including the presence of neurologic deficit, mechanism of injury, biomechanical stability, osteoligamentous integrity, and fracture morphology.³⁸ Multiple classification systems have been developed on the basis of injury mechanism and radiographic features to serve as tools for clinical decision making. These include the Allen-Ferguson Classification³⁹ and the Harris Classification⁴⁰ for cervical

spine injuries, and the three-column Denis Classification⁴¹ and AO/Magerl Classification⁴² for thoracolumbar spine injuries.

In 2005 and 2007 respectively, the Spine Trauma Study Group developed the thoracolumbar injury classification and severity score (TLICS)⁴³ and the subaxial injury classification (SLIC).⁴⁴ These scores were designed to provide a surgical candidacy appraisal based on the natural history and biomechanics of these spine injuries, and have since gained widespread acceptance in clinical practice. The three components of the scoring system include (1) injury and fracture morphology, (2) integrity of the discoligamentous complex or posterior ligamentous complex (PLC), and (3) neurological status (Tables 56.3 and 56.4). The subgroups under each category were assigned a score,

Table 56.4: The thoracolumbar injury classification and severity score.⁴³

Parameter		Points
Morphology	• No abnormality	0
	• Compression	1
	• Burst	+1 = 2
	• Translation rotation	3
	• Distraction	4
Integrity of posterior ligamentous complex	• Intact	0
	• Suspected/indeterminate	2
	• Injured	3
Neurologic status	• Intact	0
	• Nerve root	2
	• Conus medullaris (complete)	2
	• Conus medullaris (incomplete)	3
	• Cauda equina	3

with a higher score reflecting a greater perceived need for operative intervention. For both the SLIC and TLICS systems, a total score of ≥ 5 suggests benefit from surgical intervention, whereas ≤ 3 suggests benefit from conservative management. A score of 4 suggests that the injury may be managed at the discretion of the surgeon involved. The SLIC score is the classification system recommended by the AANS/CNS for its excellent inter-rater reliability and ability to communicate both clinical and radiographic information in addition to radiographic information.⁴⁵ Similarly, the TLICS score was found to have good inter-rater and intra-rater reliability among spine surgeons in a recent multicenter reliability study,⁴⁶ and is widely used around the world.

For surgical candidates, there is emerging evidence and consensus among spine surgeons in favor of early decompression within 24 hours of SCI. For many years, the timing of surgery was controversial as the benefits from early alleviation of ongoing cord trauma was balanced by concerns regarding intraoperative exacerbation of hemodynamic instability.⁴⁷ However, animal data over the decades have demonstrated a temporal relationship of spinal cord compression in behavioral recovery, spinal cord blood flow disturbances, electrophysiological recovery, and histopathological lesion.⁴⁸ Human data consisting of nonrandomized prospective controlled trials and retrospective reviews supported the safety of early surgical decompression but yielded conflicting data regarding its efficacy. The first randomized controlled trial (RCT) of

early surgical decompression in cervical SCI attempted to discern the role of early (< 72 hours) versus late (> 5 days) decompression.⁴⁹ Unfortunately, 20 of the 62 patients originally enrolled were lost to follow-up and no neurologic difference was attributed to timing of decompression.

Recently published in 2012, two prospective cohort studies were completed to discern the role of early (< 24 hours) surgical decompression. The Surgical Timing in Acute Spinal Cord Injury Study (STASCIS) is the largest multicenter prospective cohort study on the timing of surgical decompression in SCI to date, involving 313 adults with acute cervical SCI who received early versus late surgical decompression.⁵⁰ At 6 months, early surgical decompression was associated with a statistically significant 2.8 time increase in patients exhibiting at least a two-grade improvement in AIS, with no difference in acute complication rates between the two groups. A second study involved 84 SCI patients in the Ontario Spinal Cord Injury Registry program who received early versus late surgical decompression.⁵¹ Of the 55 patients with neurological examination available at rehabilitation discharge, there was also a statistically significant increase in the number of patients showing at least a two-grade AIS improvement in the early surgery group. In addition to clinical evidence supporting early surgical decompression, it is considered by many clinicians as feasible and the standard of care for incomplete SCI. In a 2010 case-based survey of 971 international orthopedic and neurosurgery spine surgeons, approximately 80% preferred to decompress an unstable, incomplete SCI (ASIA B-D) within 24 hours of injury, except in the case of central cord syndrome due to its propensity for spontaneous neurologic improvement over the ensuing weeks.⁵² A subgroup of surgeons recognized the role of ultra-early surgical decompression; specifically, 72.9% would operate within 6 hours for incomplete SCI and 46.2% would operate within this period for complete SCI.⁵² Due to emerging evidence-based data and international consensus, patients who are medically stable and appropriate for surgery should be decompressed within 24 hours of injury.

Following determination of surgical candidacy, the approach to decompression should be considered. Surgical treatment of cervical spine injuries includes anterior, posterior, or combined anterior/posterior approaches. Proponents of an anterior approach advocate its safe positioning, surgical dissection along defined tissue planes, and ventral decompression performed under direct visu-

alization, while proponents of the posterior approach cite superior biomechanism and straightforward open reduction of facet dislocations.⁵³ Several studies have compared the two approaches; most of them indicated that there were no significant differences in outcome between the two approaches.⁵³⁻⁵⁷ In a prospective randomized study in 2003, 52 patients with unstable cervical spine injuries were randomized to receive either anterior or posterior stabilization and fusion.⁵⁷ Patients in these two groups reported no difference in neurologic outcome, fusion status, changes in alignment, and pain at final follow-up. Another prospective controlled trial in 2007 randomized 42 patients with unilateral cervical facet fractures to receive anterior or posterior fixation.⁵⁸ Anteriorly treated patients exhibited somewhat less postoperative pain, a lower rate of wound infection, a higher rate of radiographically demonstrated union, and better radiographically proven alignment, but reported a risk of dysphagia in the early postoperative period. Patient-reported outcome measures did not reveal a difference between anterior and posterior fixation procedures.

Following the development of the SLIC classification, a surgical approach and treatment algorithm for subaxial cervical SCI was published by Dvorak et al.⁵⁹ Operative cervical spine injuries were categorized into three morphologic subgroups consisting of burst fractures, hyperextension injuries, and translational/rotational injuries. According to this algorithm, burst fractures would benefit from a cervical vertebrectomy with autologous or allogenic bone graft, supplemented with an anterior cervical plate. When this scenario is accompanied by SCI and attendant spinal cord compression, any retropulsed fragments can be directly visualized and removed using this approach. For hyperextension injury, with or without avulsion fractures, an anterior cervical discectomy and fusion with a supplemental anterior plate is the recommended approach. Patients with ankylosing spondylitis or DISH would benefit from supplementation with posterior long-segment instrumentation and fusion due to failure rate of up to 50% in standalone anterior instrumentation and fusion procedures.⁶⁰ The most complex and unstable group is those with translation or rotation injuries. Although many of the compression and distraction injuries can be managed with anterior surgery alone, injuries in the translation or rotation category are more commonly treated with posterior and circumferential fusion. Many of the most unstable injuries, such as teardrop fractures or bilateral facet fracture dislocations, in which either

closed or anterior open reduction are not successful in achieving anatomic reduction, are best managed with a circumferential anterior and posterior fusion. Less severe injuries such as the unilateral facet fracture dislocation may be managed with either posterior or anterior approaches alone.

In thoracolumbar spine trauma, Vaccaro et al. suggested that the decision between an anterior, posterior, and combined anterior/posterior approach depends on the neurologic status of the patient and the integrity of the PLC.⁴³ For SCI patients with anterior compression of the spinal cord and an intact PLC, an anterior operation is appropriate to optimize the degree of decompression achieved, and potentially the degree of neurologic recovery seen at follow-up. If the patient has disrupted PLC in the absence of SCI, a posterior operation can be used to restore the posterior tension band and to re-establish stability. If, however, SCI and PLC disruption is present concurrently, this situation demands first an anterior decompressive procedure, followed by a posterior stabilization. In addition, based on data from 28 patients with three-column thoracolumbar injuries, McCormack developed the load sharing classification to grade (1) the amount of damaged vertebral body, (2) the spread of the fragments in the fracture site, and (3) the amount of corrected traumatic kyphosis.⁶¹ The system identified preoperative predictors of screw breakage when short segment, posterior-placed pedicle screw implants are being used, and evaluated the need for supplemental placement of anterior strut graft.

■ TRACTION/REDUCTION OF CERVICAL SPINE INJURIES

While cervical facet dislocations constitute only about 10–15% of all cases of cervical spine trauma, the results can be particularly devastating, with approximately 37% of patients with unilateral dislocation and 90% of patients with bilateral dislocation presenting with neurological deficit.⁶²⁻⁶⁴ The immediate treatment goals include restoration of anatomical alignment and immobilization of the cervical spine to prevent further SCI and to facilitate bone healing. In light of existing class III evidence suggesting improved neurological outcomes, the AANS/CNS recommends early reduction of cervical spinal facet fractures and dislocation injuries in awake and alert patients who can undergo serial monitoring.⁶⁵

Closed reduction can be achieved through the application of traction (Gardner-Wells tongs or Halo Ring) or manipulation under anesthesia (MUA). Starting at approximately 3 lb per number of vertebrae rostral to the level of the injury, weight is then added in an incremental fashion until radiologic reduction is achieved or until reduction fails (new or worsening neurological deficit, medical instability, radiologic evidence of over distraction or patient/equipment unable to tolerate additional weight). Closed reduction of fracture/dislocation injuries by traction-reduction appears to be effective and safer than MUA. Multiple retrospective analyses demonstrated closed reduction to have an efficacy of 80%, with less than 1% of patients experiencing a permanent neurological complication and 2–4% experiencing a transient neurological complication.⁶⁵

The utility of pre-reduction MRI to exclude traumatic disc herniation and potential cord compromise during the procedure is a controversial topic. The additional information provided by MRI is balanced by risks of transportation during an unstable period and a delay in treatment. Prospective reviews have shown that pre-reduction MRI will demonstrate disc herniation in one-third to

one-half of patients with acute cervical spinal facet subluxation injuries. However, this is of ambiguous clinical value, as there is a lack of correlation between these MRI findings and neurological deterioration. MRI prior to closed traction-reduction in patients with acute cervical fracture dislocation injuries is not routinely required, but is recommended before either anterior or posterior surgical procedures when closed reduction has failed.⁶⁵

■ PHARMACOLOGIC MANAGEMENT

Numerous neuroprotective agents have been investigated through animal experimentation and human clinical studies over the past few decades. Naloxone, thyrotropin releasing hormone (TRH), nimodipine, tirilazad mesylate, GM-1 ganglioside (Sygen), and corticosteroids have undergone human RCTs to investigate their safety and efficacy profiles (Table 56.5). Despite extensive clinical interest and research in this field, only corticosteroids have gained widespread, albeit controversial, indication for use in acute SCI.

Methylprednisolone sodium succinate (MPSS) is a synthetic glucocorticoid that has been extensively studied since the 1960s. Its proposed mechanisms of action include

Table 56.5: Landmark trials for therapies in the management of acute spinal cord injury.

Treatment	Trial	Year	Enrollment	Study design	Conclusions	Clinical use
<i>Pharmacotherapy</i>						
Naloxone	Flamm et al. ¹¹⁰	1985	29	Phase I— <i>pilot study</i>	No significant improvement in neurologic function	No
	Brckken et al. ⁶⁸ <i>NASCIS II</i>	1990	487	Phase III RCT	Unlike MPSS, no clinical benefit was ascribed to naloxone	
TRH	Pitts et al. ¹¹¹	1995	20	Phase II RCT— <i>pilot study</i>	No significant improvement in neurologic function	No
Nimodipine	Petitjean et al. ¹¹²	1998	106	Phase III RCT	No benefit can be ascribed to MPSS or nimodipine	No
Gacyclidine	Tadie et al. ¹¹³	1999	280	Phase II RCT	No significant improvement of motor recovery with incomplete cervical SCI	No
Tirilazad mesylate	Bracken et al. ¹¹⁴ <i>NASCIS III</i>	1997	499	Phase III RCT	No significant difference in neurologic recovery compared to MPSS	No
GM-1 ganglioside	Geisler et al. ⁷⁸	1991	37	Phase I RCT— <i>pilot study</i>	No significant improvement in neurological outcome	No
	Geisler et al. ⁷⁹ <i>The Sygen Multicenter Acute Spinal Cord Injury Study</i>	2001	797	Phase III RCT	No significant trend toward early recovery and neurological improvement

<i>Treatment</i>	<i>Trial</i>	<i>Year</i>	<i>Enrollment</i>	<i>Study design</i>	<i>Conclusions</i>	<i>Clinical use</i>
MPSS	Bracken et al. ⁶⁷ <i>NASCIS I</i>	1984	330	Phase III RCT	No significant difference in neurologic outcome of high- and low-dose groups	Center and surgeon dependent
	Bracken et al. ⁶⁸ <i>NASCIS II</i>	1992	487	Phase III RCT	No significant difference in primary analysis <i>Post-hoc analysis:</i> significant improvement in motor recovery if MPSS is administered within 8 hour of injury	
	Bracken et al. ⁶⁹ <i>NASCIS III</i>	1997	499	Phase III RCT	<i>Post-hoc analysis:</i> significant improved neurologic outcome with 48-hour MPSS infusion for patients 3–8-hour post SCI	
	Otani et al. ¹¹⁵	1994	158	Phase III RCT	No significant difference in primary analysis	
	Petitjean et al. ¹¹²	1998	106	Phase III RCT	No benefit could be ascribed to MPSS or nimodipine	
<i>Evolving therapies</i>						
Riluzole	Fehlings et al. ⁸⁷ <i>NACTN for Treatment of Spinal Cord Injury</i>	2012	36	Phase I— <i>pilot study</i>	Promising preclinical data, pending final analysis	No
Minocycline	Casha et al. ⁸⁴	2012	52	Phase II RCT— <i>pilot study</i>	No significant motor improvement for cervical SCI, greatest difference in cervical motor-incomplete injury	No
Cethrin	Fehlings et al. ⁹⁰	2011	48	Phase I/II — <i>pilot study</i>	No significant motor improvement for complete cervical SCI	No
Therapeutic hypothermia	Dididze et al. ¹⁰⁶ <i>The Miami Project to Cure Paralysis</i>	2013	35	Phase I/II — <i>pilot study</i>	No significant improvement in motor function at 1 year following complete cervical SCI	No
	<i>ARCTIC</i>	2013	200 (proposed)	Phase II/III RCT (<i>pending approval</i>)	Future trial for efficacy and safety of modest hypothermia initiated within 6 hour of SCI	
CSF drainage	Kwon et al. ¹⁰⁹	2009	22	Phase I/II RCT — <i>pilot study</i>	Establishment of safety	No

(ARCTIC: Acute rapid cooling therapy for injuries of the spinal cord; CSF: Cerebrospinal fluid; MPSS: Methylprednisolone sodium succinate; NACTN: North American Clinical Trials Network; NASCIS: National acute spinal cord injury study; RCT: Randomized controlled trial; TRH: Thyrotropin releasing hormone).

attenuating neuronal membranes, decreasing tumor necrosis factor alpha release, improving spinal cord perfusion, and reducing neuronal calcium influx.⁶⁶ It has been investigated in a few human RCTs, including the landmark National Acute Spinal Cord Injury Study (NASCIS) I–III. Published in 1984, the NASCIS I trial compared

high- and low-dose MPSS regimen, administered for the first 10 days following SCI, without comparison to placebo.⁶⁷ At 6 months and 1-year follow-up, the two groups had similar neurologic outcomes, but the higher dose group had increased wound infection complication rates. Due to preclinical data suggesting that an even higher dose

of MPSS would be required for efficacy, the NASCIS II trial was completed in 1990 to investigate MPSS against naloxone and placebo.⁶⁸ The overall analysis did not show statistical significance, although the subgroup that received MPSS within 8 hours of injury revealed a modest but statistically significant motor and sensory improvement at 6 months, with persisting motor improvement at 1 year. This post hoc analysis finding led to the NASCIS III trial, which included SCI patients only within 8 hours of injury, to investigate the length of therapy and effects when coadministered with tirilazad mesylate, an aminosteroid with lipid peroxidation inhibiting properties.⁶⁹ The study compared the NASCIS II protocol of 24-hour administration protocol with a longer 48-hour protocol. Analysis of the results concluded that the 24-hour MPSS infusion was adequate for patients presenting within 3 hours of injury, but patients presenting 3–8 hours after injury would benefit from a longer course of infusion over 48 hours. Criticisms of the NASCIS trials point to the controversial data on corticosteroid benefits that were observed only in subgroup analysis. Furthermore, numerous prospective and retrospective analyses of MPSS administration for SCI revealed increased rates of wound infections, sepsis, pulmonary complications, gastrointestinal complications, urinary tract infections, and acute corticosteroid myopathy.^{70–75}

The 2013 AANS/CNS guidelines on the pharmacologic treatment of SCI do not recommend the routine use of MPSS due to lack of class I/II evidence.⁷⁶ However, in the context of inconsistent benefits, the role of corticosteroids in SCI continues to be controversial, heavily debated, and surgeon-dependent. It remains an option for nondiabetic and immunocompetent patients presenting within 8 hours of nonpenetrating SCI. As per NASCIS II/III protocol, patients presenting within 3 hours of injury should receive 30 mg/kg bolus followed by infusion at 5.4 mg/kg/h for 24 hours, while those presenting between 3 and 8 hours of injury would benefit from a longer infusion of 48 hours.

GM-1 ganglioside (Sygen) is a member of a heterogeneous family of complex glycosphingolipids, which are abundant naturally in neurons. In laboratory studies, Sygen reduces glutamate-mediated excitotoxicity and subsequent apoptosis, and also mimics endogenous neurotrophic factors, which stimulate nerve fiber growth and repair.⁷⁷ It has been explored as a therapy for multiple neurodegenerative diseases, yielding promising animal data. In 1991, a small phase II trial of GM-1 in SCI suggested improved neurological recovery.⁷⁸ The following year, the largest human phase III RCT for SCI to date, with an

enrollment of almost 800 participants, was initiated to evaluate the role of low-dose and high-dose Sygen against placebo.⁷⁹ Although a nonsignificant trend toward greater mobility on the Modified Benzel Walking Scale was noted at 6 months follow-up, no further investigations were completed and Sygen is not used clinically around the world.

EMERGING THERAPIES

To further understand and advance the field of SCI management, several novel treatments are currently undergoing investigation. Neuroprotective agents including minocycline, riluzole, and Cethrin, as well as techniques of CSF drainage and therapeutic hypothermia have shown efficacy in animal models and hold promise for human translation.

Minocycline is a synthetic tetracycline antibiotic and metalloproteinase inhibitor. It has been demonstrated in laboratory studies to have anti-inflammatory and anti-apoptotic properties, acting to suppress cytokine production, microglial activation, and neuronal death.^{80–83} The first human translation of this information was a single-center, double-blind RCT involving 52 patients who were either administered intravenous minocycline or placebo for 7 days. The results from this phase II study were published in 2012, and minocycline administration was associated with a tendency toward improvement across several outcome measures, approaching significance for motor improvement in the cervical incomplete SCI group.⁸⁴ These data are encouraging and provide foundation for future investigation.

Riluzole is a benzothiazole sodium channel blocker currently used to treat ALS.⁸⁵ It is believed to mitigate neurotoxic mechanisms by inhibiting presynaptic glutamate release and increasing high-affinity glutamate uptake, therefore reducing motor neuron degeneration.⁸⁶ A human trial has recently demonstrated its safety and promise, and a multicenter Phase II/III RCT examining its clinical translation is under way.⁸⁷

Cethrin[®] is a combination of fibrin sealant Tisseel[®] and Rho-inhibitor BA-210 that can be applied to the dura at the time of surgical decompression. Following SCI, myelin and extracellular matrix inhibitors trigger collapse of the growth cones of regenerating axons via the Rho pathway.⁸⁸ BA-210 is a bacterial-derived toxin and cell-permeable form of C3 transferase, which inhibits the Rho pathway, effectively antagonizing all known myelin and extracellular matrix inhibitors.⁸⁹ A phase I/IIa trial involved 37 com-

plete SCI patients who received intraoperative Cethrin an average of 53 hours following injury. At 6 months post injury, 27% of patients who received Cethrin improved by ≥ 1 ASIA grade, with no associated increase in complications.⁹⁰ A phase III RCT is being designed to investigate the role of Cethrin on a larger scale.

Stem cell therapy has garnered considerable attention in preclinical and human studies as a method of cell replacement in addition to preservation. Stem cells regulate gliosis and scar formation, prevent cyst formation, and enhance axon elongation.⁹¹ Through secretion of anti-apoptotic and proangiogenic neurotrophic factors, they also cultivate an environment supportive of neural plasticity and regeneration.⁸ In addition to supporting and preserving surviving cells, they also replace damaged neurons and glial cells, playing an important role in the restoration of neural circuitry by remyelination of surviving axons, and bridging of lesion cavities across gliotic and scarred tissues.⁹²

Bone marrow stromal cells, olfactory ensheathing cells, Schwann cells, activated autologous macrophages, human embryonic stem cells, and tissue-derived adult neural stem cells have all been studied in preclinical studies, with no type showing superiority.⁹¹ More than a dozen human trials have begun with these stem cell types for treatment of both acute and chronic SCI.^{8,47} Prior to widespread translation of this therapy, challenges regarding their propensity for tumor formation, creation of abnormal circuitry leading to dysfunction, and the ethical dilemma surrounding their harvesting and use must be overcome.⁹¹ The development of induced pluripotent stem cells in 2006 allows any adult somatic cell type to be transformed into an embryonic stem cell through the introduction of four genes (Sox2, klf4, c-Myc, and Oct4).⁹³ This technology has been an important breakthrough as it avoids ethical issues inherent to fetal cell sources and also allows for autotransplantation obviating the need for immunosuppressants. Extensive ongoing research continues to contribute to our knowledge of the properties of stem cells, and their role in both host interaction and regenerative potential.

Therapeutic hypothermia has been intensively studied in animal models and human conditions of cardiac arrest and TBI.⁹⁴ Laboratory investigations have demonstrated that hypothermia reduces cellular energy requirements, slows enzymatic activity, and decreases cerebral metabolic rate and glucose requirements.^{95,96} Hypothermia for animal models of SCI exhibited an association with attenuated glutamate excitotoxicity, decreased polymorphonuclear

leukocyte invasion and neuroinflammatory response, and reduced vasogenic edema and hemorrhage at the primary site of injury.⁹⁷⁻¹⁰⁵ Interest in human translation of this information led to a phase II single-center study on the efficacy and complications of hypothermia for acute complete cervical SCI.¹⁰⁶ A total of 14 patients with complete SCI were recruited and moderate systemic hypothermia of 33°C was achieved in all patients for the first 48 hours of injury. Neurologic outcome was matched to data from historical cohorts. Recently completed, the study showed no increase in complications associated with hypothermia. A phase III RCT is being planned and designed to investigate hypothermia in a larger, multi-center level.

Cerebrospinal fluid drainage is a technique to lower intrathecal pressure, and is routinely performed in thoracoabdominal aortic aneurysm surgery to prevent spinal cord ischemia and paraplegia.^{107,108} In SCI, it is believed to increase spinal cord perfusion pressure, attenuate ischemia and provide neuroprotection. A phase I/II trial involving 22 patients was completed to study intrathecal pressure changes before and after surgical decompression, as well as to evaluate its safety, feasibility, and efficacy.¹⁰⁹ CSF drainage was not associated with adverse effects; however, in this underpowered study, neurologic improvement was not observed.

CONCLUSION

The initial assessment and acute management of SCI play a key role in stabilizing patient's clinical status, mitigating secondary injury, and improving long-term survival and neurologic outcomes. Initial management should focus on early spinal immobilization, treatment of respiratory distress and hemodynamic instability, and admission to an intensive care setting for monitoring. Due to the physiologic complexity of acute SCI, the treatment regimen should consist of a comprehensive combination of closed or open decompression and neuroprotective pharmacologic therapy targeting various stages of the primary and secondary injury cascade. For appropriate surgical candidates who are medically stable, surgery should be performed within 24 hours of SCI to establish normal spinal anatomy and decompression. Corticosteroid administration within 8 hours of SCI remains a controversial topic, and any benefit is balanced by pulmonary, infectious and wound healing complications. Lastly, multiple neuroprotective agents and treatment modalities including

CSF drainage and therapeutic hypothermia demonstrate highly encouraging preliminary laboratory and phase I/II data, and lay the foundation for future investigation and possible incorporation into clinical treatment.

- » Cellular Therapies for Acute tSCI
- » Timing of Surgical Intervention in Acute SCI

BACKGROUND

Traumatic spinal cord injury (tSCI) is not only devastating for patients and their families, but it is also associated with tremendous societal impact. In North America, the incidence of spinal cord injury (SCI) varies geographically between 27 and 48.4 cases per million individuals.^{1,3,5,7,9,11} The average lifetime costs of care range between 1.47 million and 3.03 million in Canadian dollars.^{12,13} These injuries impose a substantial toll on the individual and lead to increased healthcare utilization, lower rates of social participation, and lower rates of employment than the uninjured population.

Despite the significance of this type of injury to individuals, their families, and society as a whole, there are no clearly accepted and proven treatments to reduce the severity of tSCI, nor is there any proven regenerative or curative therapy available. This leaves caregivers with the unenviable task of explaining that all we can do is simply support the natural recovery of the spinal cord by optimizing the environment around it (surgical stabilization and decompression) and supporting its general physiological functions (perfusion, oxygenation). When the patient and their family ask “what can you do, Doctor, to repair this injured spinal cord?” the honest answer is “very little, beyond encouraging optimal natural recovery.”

PHARMACOLOGIC NEUROPROTECTIVE THERAPIES AFTER ACUTE SCI

The pharmacological neuroprotection of a potentially injured spine and spinal cord begins at the accident scene, where the immediate goal is to extract the patient from any imminent danger and ensure that fundamental aspects of resuscitation at the scene are performed. This may involve elements of both basic life support (BLS) and advanced life support (ALS). BLS involves noninvasive therapies such as spinal immobilization and external protection of the airway, while ALS adds intubation and assisted ventilation, as well as intravenous fluid and medication administration. Intravenous fluids are frequently administered at the scene of injury and inotropic support for maintaining blood pressure may also be initiated prior, or on the way, to a specialized SCI center. Unstable patients may have to be diverted to the nearest regional center where they can be stabilized and then be transported, when hemodynamically and physiologically stable, to a tertiary care center.

By maintaining oxygenation and perfusion, the goal is to minimize any further neurologic injury. In developing countries, it is likely that many tSCIs either develop or deteriorate during extraction and transport to medical facilities possibly due to either lack of recognition, lack of immobilization or failure to provide cardiorespiratory

support. Periods of profound hypotension, bradycardia, and hypoxemia that often can occur at the scene of the injury and in subsequent hours likely inhibit natural recovery of the tSCI and at worst, may lead to progression of the extent and severity of the neurological injury. Rapid transport time to a definitive center of excellence in tSCI care is associated with improved neurological and overall function.^{20,22}

Hypotension in the acute trauma patient is assumed to be of a hemorrhagic etiology until proven otherwise. The chest, abdomen, and pelvis should be examined, as they are the most likely sources of blood loss. Hypotension in the presence of bradycardia without any overt signs of blood loss likely signifies neurogenic shock, typically seen in SCIs that occur cephalad to T4. Although no universally accepted hemodynamic parameters define neurogenic shock, most studies use a systolic blood pressure <100 mm Hg and define bradycardia as a heart rate of <50 beats per minute in patients without any other cause of shock.²³

Regardless of its etiology, hypotension must be aggressively corrected to minimize secondary ischemic damage to the spinal cord. In patients whose blood pressure is unresponsive to crystalloid, universal donor blood group (group O, Rh negative) is recommended until matched blood products are available. Early administration of blood products is of particular importance in spinal cord injured patients to maximize the oxygen-carrying capacity, thereby minimizing the secondary ischemic and hypoxic injury to the vulnerable cord.²⁴ Invasive monitoring from arterial and central venous access is imperative to guide interventions. Once the patient is normovolemic, the maintenance of a mean arterial pressure (MAP) of 85–90 mm Hg is recommended for 5–7 days, although it is recognized that the clinical evidence to support this target MAP is relatively weak.^{27,28} Ongoing hypotension can be managed with vasopressors such as dopamine, norepinephrine, or phenylephrine, whose agonist activity raises the systemic vascular resistance. This can be followed by the oral agonist midodrine, which can be weaned over a couple of weeks as hemodynamic stability is achieved. Low cardiac output resulting from persistent bradycardia can be treated with atropine.

When a tSCI occurs, the spinal cord undergoes two types of insults referred to as the primary and secondary injuries. The primary injury, sustained from the initial trauma, and resulting spinal cord compression, initiates a cascade of local and systemic factors that lead to ischemia, inflammation, production of free radicals, increase in

membrane permeability, loss of autoregulation, and pathologic electrolyte shifts, all of which can profoundly modulate the extent of injury from the initial mechanical stress.²⁹ This cascade of events is known as the secondary injury. It develops over minutes to weeks following trauma, and is where the opportunity for neuroprotection and therapeutic intervention lie.^{29,31}

Methylprednisolone

One of the most tragic examples of our failure to effectively translate potentially promising neuroprotective preclinical findings into clinical practice is the tale of methylprednisolone. Methylprednisolone sodium succinate (MPSS) is a pharmacological neuroprotective agent that is administered intravenously. This steroid has been studied extensively in animal models, and has been reported to act through a number of different mechanisms, including the reduction of lipid peroxidation, improvement in spinal cord blood flow, and attenuation of inflammation.^{29,32,34,35}

The administration of MPSS to acute SCI patients was tested in three large-scale prospective randomized double-blinded multicenter clinical trials: the National Acute Spinal Cord Injury Studies (NASCIS) I, II, and III.^{36,38,39} The first study failed to reveal any neurological improvements with MPSS, and it was later suggested from animal studies that this was due to the administration of subtherapeutic doses. In the NASCIS II trial, the dose was increased to a 5.4 mg/kg bolus, followed 45 minutes later by a 24-hour infusion of 30 mg/kg. This second study again reported a negative primary outcome; however, upon post hoc analyses, the authors reported that patients treated within 8 hours from the time of injury experienced significant motor and sensory improvements. MPSS rapidly became a standard of care in the treatment of acute tSCI following the release of the NASCIS II results to the media and publication in a high impact journal.³⁶ Unfortunately, a lack of appropriate scrutiny through the peer review and editorial review processes led to a debate in the literature, ambiguity and the eventual repudiation of recommendations for the use of this drug.^{1–11} The NASCIS III study refined the administration protocol by reporting greater motor and functional improvement when the infusion was extended to a 48-hour period in patients whose treatment was initiated 3–8 hours post injury (24-hour infusion was shown to be equivalent for those treated at less than 3 hours post injury). The longer infusion time did, however increase the incidence of severe sepsis and pneumonia.

The NASCIS trials have been heavily criticized for methodological issues including inadequacies in randomization (e.g. large difference in severity of neurologic deficits for patients in each treatment arms), deficiencies in statistical analyses (e.g. arbitrary 8-hour time window suspected to have been decided after a post hoc analysis), and poorly defined clinical end points (scoring of motor improvements not clinically relevant).^{2,4,8,10,12,13} Numerous societies have performed exhaustive reviews of the NASCIS trials and other human SCI studies, and have concluded that MPSS should not be considered a standard of care, but rather a treatment option.¹⁴⁻¹⁷ The majority of Canadian surgeons have since abandoned the use of MPSS, although its use in the United States continues, in large part due to the medicolegal climate and fears of litigation.^{18,19} This issue therefore is not resolved and remains a glaring example of how tSCI clinical trials that intend to further therapeutic alternatives can profoundly frustrate and potentially harm the care of patients. In fact, the increased risk of mortality when MPSS is used in acute head injury has been demonstrated in the corticosteroid randomisation after significant head injury (CRASH) trial.²⁰⁻²² The identification of this substantial risk profile for MPSS when used in traumatic head injury has led to newly published guidelines discouraging the use of MPSS in SCI.^{17,23}

Minocycline

Minocycline is a tetracycline antibiotic that has been used clinically for many years for other indications. It is thought that minocycline increases interleukin-10 and decreases tumor necrosis factor alpha expression, preventing the exacerbation of the secondary injury in SCI by attenuating neuroinflammation and inhibiting apoptosis.²⁴⁻²⁶ Other proposed mechanisms of action include the inhibition of excitotoxicity, oxidative stress, apoptotic pathways, and inflammatory mediators released by activated microglia.^{25,27,28} Minocycline has also been reported to reduce microglial activation.^{25,29}

In animal models, minocycline has been shown to improve neurological and histological outcomes, reduce neuronal and oligodendroglial apoptosis, decrease microglial activation and reduce inflammation.²⁹⁻³¹ Reduced tissue damage, lesion size and apoptosis at the site of injury have been correlated to improved functional outcomes.^{26,29,32-35}

A recent phase II placebo-controlled randomized trial of minocycline in acute traumatic SCI patients has demonstrated its safety.³⁶⁻³⁹ Improvement in some subgroups of

patients, particularly cervical incomplete injuries, has been encouraging. A multicenter phase II clinical trial has been initiated in Canada.

Riluzole

Riluzole is a benzothiazole anticonvulsant that is currently approved by the FDA for use as a neuroprotective agent in amyotrophic lateral sclerosis. It functions as a sodium channel blocker that attenuates secondary damage by decreasing intracellular sodium and inhibiting presynaptic calcium-dependent glutamate release. In animal models, it has been shown to increase sparing of gray matter and improve locomotor function. A recently published prospective, multicenter phase I trial, was undertaken by the North American Clinical Trials Network to investigate the pharmacokinetics, safety, and to obtain pilot data on the effects of riluzole on neurological outcome in acute tSCI. This study demonstrated the drug's safety and again provided promising findings of neurological recovery.^{36,40} A prospective multicenter clinical trial has been initiated.⁴¹

Erythropoietin

Erythropoietin (EPO) is a glycoprotein hormone that has a hematopoietic effect that results in increased red blood cell production. Erythropoietin is administered in intravenous and subcutaneous preparations and is reported to promote tissue protection in response to hypoxia and improve locomotor performance in animal models.⁴² A single dose of EPO immediately after SCI improved motor function recovery, decreased lesion severity, and increased neuronal regeneration in a rat contusion model of SCI.⁴³ EPO has also been shown to have anti-inflammatory, antioxidant, and antiapoptotic properties.⁴² A small multicenter comparative study of EPO and methylprednisolone in patients with severe motor complete tSCI began in 2008. Recruitment of subjects for this study, however, was aborted at the time of this writing.⁴⁴

Magnesium

Magnesium acts as an N-methyl-D-aspartate receptor antagonist. It is thought to attenuate excitotoxicity by limiting free radical production and glutamate release, and reduces apoptosis.⁴⁵ High-dose magnesium administration after SCI resulted in significant functional recovery, reduction in apoptosis, and lipid peroxidation.⁴⁶ A combination of magnesium and polyethylene glycol has been developed for administration to humans with SCI,

allowing lower doses to be administered.⁴⁷ A phase I study of polyethylene glycol and magnesium in healthy human volunteers has been completed but not published. A phase II study in cervical SCI patients was initiated in 2013.

Nogo-A Antibodies

Anti-Nogo-A antibodies are directed against molecules that inhibit neurite regrowth. Specifically, they are felt to inhibit the activity of Nogo-A, an inhibitory constituent within central nervous system (CNS) myelin that impedes axonal regeneration and/or sprouting. There has been a nonrandomized, multicenter clinical trial in patients with ASIA A thoracic and cervical SCI completed in Switzerland. Treatment was initiated between 7 and 14 days post injury. Antibody was administered by means of an intrathecal infusion over weeks, or by repeated bolus intrathecal injections. A study began in 2006 and was completed in 2011. No results were published at the time of this writing.⁴⁸

CELLULAR THERAPIES FOR ACUTE tSCI

Cell transplantation into the injured spinal cord is another area of significant research interest. Cells transplanted into the spinal cord may play a number of potential neuroreparative roles. For example, they may secrete neurotrophic factors and create a permissive environment for axonal sprouting/regeneration by “bridging” the injury site, or they may remyelinate demyelinated (but otherwise intact) axons to improve signal transduction across the injury.

The use of stem cell technology has created much excitement within the SCI field, as the ability to differentiate them into many different cell types raises the potential for them to even replace lost neurons and regenerate axons that might act as “relays” across the injury site.⁴⁹

A large variety of cell substrates have shown promise in preclinical models of SCI, including Schwann cells, olfactory ensheathing cells, mesenchymal stem cells, neural stem cells, and embryonic stem cells.⁵⁰ A clinical trial of oligodendrocyte progenitor cells, derived from human embryonic stem cells, was initiated in October 2010 by Geron Corporation (Menlo Park, CA); however, the trial was halted just over a year later due to financial considerations after enrolling five patients. A clinical trial of neural stem cells was initiated in Zurich, Switzerland, sponsored by Stem Cells, Inc., and at the time of this writing had enrolled four patients. A clinical trial of Schwann cells has recently been initiated by the Miami Project to cure paralysis. Like

the pharmacologic treatments, it will still take many years before evidence of efficacy will be established in such clinical trials of cell transplantation therapies.

Autologous Incubated Macrophages (Proneuron)

In response to injury, the macrophage-mediated immune response is reduced in the CNS as compared with the more actively regenerative peripheral nervous system. It was thought that manipulation of macrophage activation by monocyte cocubation with peripheral nervous system tissue would potentially facilitate neural regeneration. Rodent studies suggested improved regeneration of nerves exposed to macrophages, activated by incubation with peripheral nerves.

A clinical trial to determine the efficacy and safety of autologous incubated macrophage treatment enrolled eight participants with complete SCI who were treated with autologous macrophages, which were prepared by cocubating peripheral blood monocytes with harvested autologous skin. This study failed to show a significant difference in primary outcome between the two groups. In fact, the control group demonstrated superior neurological conversion rates.

TIMING OF SURGICAL INTERVENTION IN ACUTE SCI

Based on the pathophysiology of secondary injury after acute SCI, it is intuitive to think that early decompression of the spinal cord would be an effective neuroprotective strategy. Many animal studies have demonstrated that early decompressive surgery diminishes the extent of secondary injury and improves neurological outcomes, although the majority of these studies have utilized models of low velocity compression rather than the more clinically relevant high-velocity contusion.⁵¹⁻⁵⁴ Some have even noted that this benefit is inversely proportional to the time from injury to decompression.^{54,55} Despite this, it has been difficult to demonstrate in clinical studies of human SCI a significant neurologic benefit that results from early surgical decompression. There are many potential reasons for this. Firstly, human injuries occur with considerably higher and faster biomechanical forces than are simulated in animal studies, and hence the primary injury in humans is likely to be more severe and leave less tissue amenable to the neuroprotective benefits of surgical decompression.

Secondly, the definition of what constitutes “early surgical decompression” has not been well established, and even today there remains wide variability in the time at which SCI patients have surgery.

There are large practical difficulties in designing and executing a study, in which timing of surgery can be evaluated, as most clinicians would be unwilling to randomize a patient to a later decompression, when earlier surgery is feasible and practical. Patients are not likely to agree to be randomized to either early or late surgery. In an international survey of spine surgeons, over 80% of the respondents indicated a preference to surgically decompress the spinal cord within 24 hours and thus, there is a profound lack of clinical equipoise in relation to timing of surgery. In fact, for an incomplete cervical SCI, 72.9% of respondents felt that decompression should be achieved within 6 hours, while 46.2% felt that this sort of early decompression should be achieved for complete cervical SCI as well.⁵⁶

Recently, the Surgical Timing in Acute Spinal Cord Injury Study (STASCIS) was published,⁵⁷ which represents the largest prospective multicenter cohort study comparing the neurologic outcomes of patients with cervical SCI receiving “early” (<24 hours) versus “late” (over 24 hours) surgical decompression. The 313 patients enrolled were not randomized to a specific treatment arm. Instead, the decision of surgical timing was left to the enrolling surgeons and was often dependent on the individual’s circumstances (time for transfer to hospital, time required to obtain adequate imaging, and discretion of the attending spinal surgeon). 19.8% of patients in the early decompression cohort showed a ≥ 2 AIS grade improvement compared to 8.8% in the late decompression group. After a multivariate analysis was performed to account for preoperative neurological status and steroid administration in both groups, the odds of having two or more AIS grades of improvement were 2.8 times higher in those who were decompressed early. The secondary outcomes consisted of in-hospital postoperative complication rates and mortality: the early group experienced a complication rate of 24.2% compared to 30.5% in the late surgery group. When the complications data are looked at more closely, “construct failure requiring surgery” is reported to have occurred in 6.3% versus 2% of cases in early versus late surgery, respectively, which likely relates to the lack of specific equipment and experienced personnel when surgery is expedited. One death occurred in each group in the 30-day post-injury period. Of note, the STASCIS study excluded patients with severe concomitant injuries and was restricted to cervical injuries.⁵⁷

A recent systematic review and meta-analysis of the timing to surgery has been published and suggests that early surgery performed up to 24–72 hours after injury was associated with an almost six motor point improvement when compared to surgery performed later. There was a longer length of hospital stay associated with late surgery. The authors caution that these results are not robust and should be interpreted cautiously.⁵⁸

SUMMARY

Intensive scientific research has shed light on the complex pathophysiology of SCI, and has led to the development of a number of experimental treatments that are under evaluation in clinical trials. Although no pharmacologic neuroprotective or neuroregenerative therapies have been validated for clinical use, there are some promising investigations underway.

Likely, some form of combinatorial therapy that includes pharmacologic interventions at specific time points following injury as well as best clinical practices, such as hemodynamic support, may ultimately benefit patients.

For the time being, it appears to be clear that there is no dramatic detriment to early surgery from either a neurological outcome or a health systems perspective. When it is feasible to do so, and the resources are available and the system of care permits it, early surgical intervention should be encouraged.

- » Patterns of Injury and Treatment Recommendations

INTRODUCTION AND EPIDEMIOLOGY

Spine trauma and spinal cord injury (SCI) is relatively rare in the pediatric population. In the United States, <4% of SCI occur in patients younger than 15 years of age.¹ Cervical spine trauma is responsible for 60–80% of pediatric SCI and results in significant lifelong disability and healthcare cost.² The incidence of SCI in the United States between the years of 1997 and 2000 was 1.99 per 100,000 children, compared to 1 per 1 million children in Canada.^{3,4} This translates to approximately 1,455 new SCI in pediatric patients per year in the United States.⁴ Boys are more than twice as likely than girls to suffer an SCI, and Asian children have the lowest incidence of SCI (0.36/100,000) compared to African American children who have the highest (1.53/100,000). Children younger than 11 years of age with a neurological injury secondary to cervical spine trauma have a 5.1 times higher risk of death than do patients older than 11.⁵

A study of 103 consecutive pediatric patients with cervical SCI found that motor vehicle accidents were the most common mechanism of injury representing 52% of all patients.⁶ Of the 18.5% of the children who presented with fatal SCI, 95% of the injuries were the result of motor vehicle accidents.⁶ Interestingly, seat belts do not appear protective for pediatric SCI.⁷ Sport injuries were the second most common etiology, accounting for 27% of patients. American Football has been the subject of much attention, both in the lay press and academic literature, as an etiology

of SCI in the pediatric population. In 2010, there were seven permanent SCI associated with American Football, five in the high school population and two in collegiate athletes.⁸

The rule changes adopted in 1976 that banned spear tackling have been associated with an overall decrease in SCI in American Football.⁹ In 2010, the overall risk of cervical SCI in high school and college football players was 0.33 and 2.66 per 100,000 participants, respectively. Despite the focus on American Football as an etiology of athletic SCI, recreational diving is probably a more common cause of sport-associated SCI; in one study, SCI resulting from recreational aquatics represented 66% of all athletic SCI compared to only 6% from football.⁹ Similarly, nearly twice as many cervical spine fractures and dislocations were caused by diving compared to football¹⁰ in a retrospective study of 41 years of data from the Mayo Clinic.⁵

Child abuse is a rare cause of SCI, and is typically seen in infants and young children. Spinal cord injury resulting from child abuse is frequently associated with head injuries and with multiple extremity fractures.¹⁰

ANATOMICAL CONSIDERATIONS

Because of anatomical differences, injuries to the occipital-cervical complex (OCC)—i.e. the occiput-C1-C2—appear to be more common in children than adults. Compared to adults, children not only have an increased ratio of head to

Fig. 58.1: Anatomical differences observed in plain radiographs in the pediatric spine.

body mass and flatter slope of the C1 superior facet joints, but also have increased ligamentous laxity and decreased posterior musculature, all of which contribute to the preponderance of upper cervical spine injuries in children (Fig. 58.1).^{11,12} Ligaments, including the transverse ligament of the atlas, alar and apical ligaments, and the tectorial membrane, are the primary stabilizers of OCC, and atlanto-occipital dissociation (AOD) results from their disruption. Upper cervical spine injuries in children are associated with increased rates of mortality.¹³ Figure 58.1 illustrates unique radiographic features of the cervical spine; note that a Power's ratio >1 is suggestive of anterior AOD.

There is a significant mismatch between the elasticity of the pediatric spinal column and the spinal cord. In a cadaveric study, Leventhal found that the spinal column of a newborn could be stretched 2 inches, while the spinal cord itself could only stretch 0.25 inches before rupture.¹⁴ This anatomical difference is hypothesized to be responsible for the increased incidence of spinal cord injury without radiographic abnormality (SCIWORA) in children, accounting for up to one third of SCI in the pediatric population.³ It is important to recognize that SCIWORA, as originally described, did not include the use of magnetic resonance imaging (MRI).^{14,15} Although MRI can frequently identify ligamentous injuries in patients with SCIs, it is still not 100% sensitive, and reports of patients with complete spinal cord transection with normal extraneural findings can be found.¹⁶ Severe SCIWORA generally has a poor prognosis for recovery and bracing has been shown to have little benefit.¹⁷ Given that MRI has

become the standard of care in the evaluation of patients with SCI, for the remainder of this chapter the term SCIWORA will refer to patients with no evidence of extraneural injury on any imaging modality, including MRI.

The disks of the pediatric spine are more resistant to injury than the vertebral bodies.¹⁸ The occurrence of traumatic intraosseous disc herniations, i.e. Schmorl's nodes, reveals the greater strength of the annulus fibrosis compared to the cartilaginous endplate. The more resilient disks in children permit the distribution of compressive forces over multiple levels, leading to the observation of multilevel compression fractures in children.¹⁹

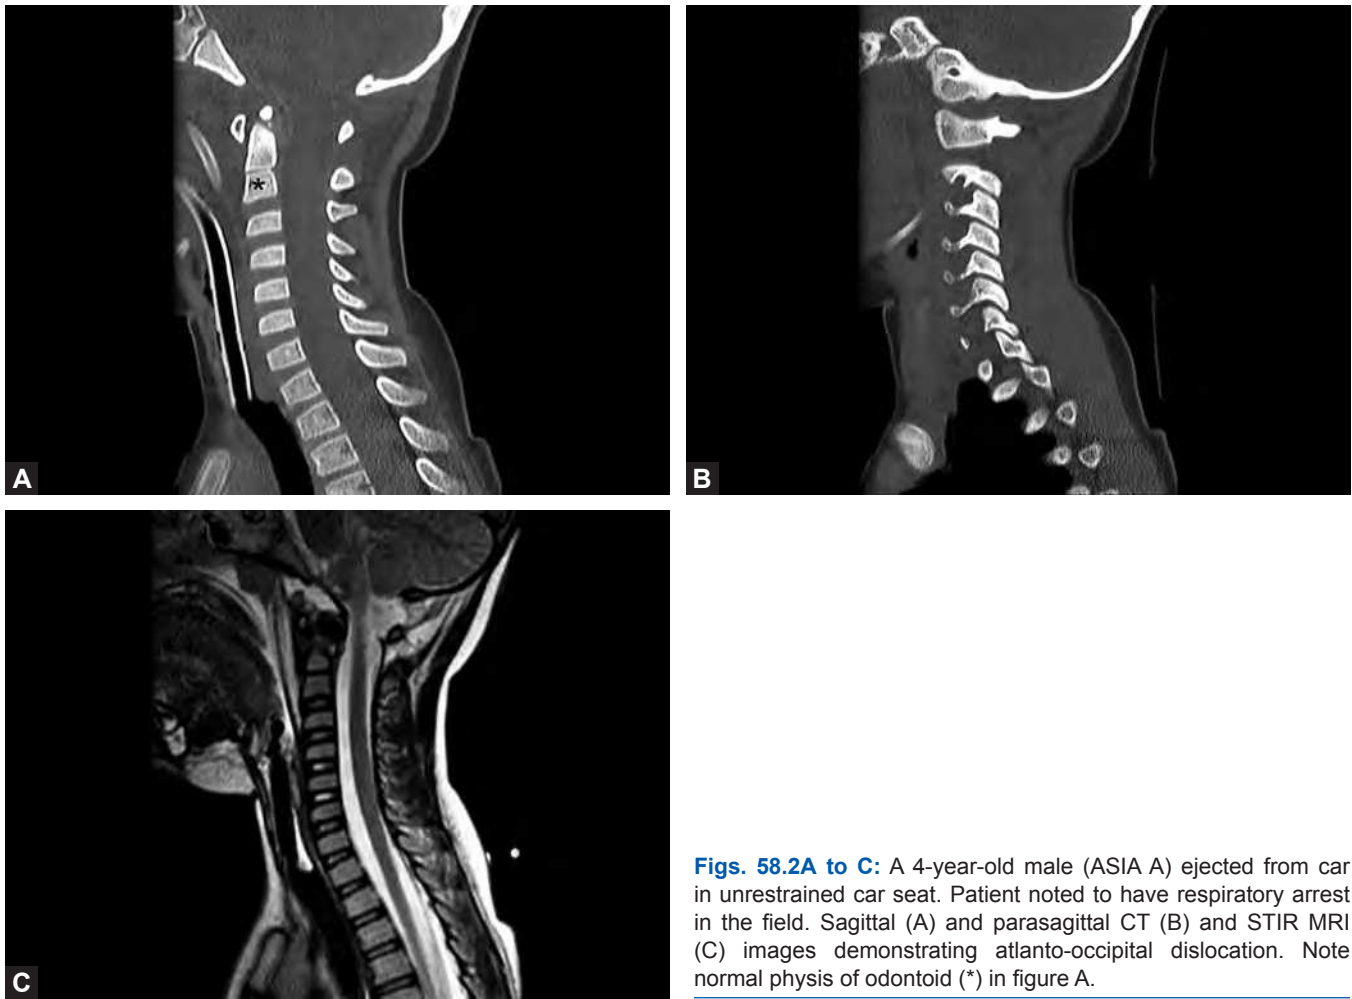

Although it is commonly held that children have an inherently better capability of recovering from neurological injury than adults, this has not been clearly demonstrated in the literature. As in adults, the final neurological outcome is most dependent on the extent of injury. Incomplete injuries have a better prognosis for recovery than complete injuries.³ A recent review by Parent et al. concluded that the evidence of superior neurological recovery in children was "very slight."¹³

Scoliosis following pediatric SCI is commonly observed, and is thought to be secondary to loss of trunk muscle control. The reported incidence of scoliosis following pediatric SCI varies in the literature from 23% to 97%,^{20,21} although the rate is clearly greater than the 5% incidence of post-SCI scoliosis observed in adults.²⁰ Children who have not undergone their pubertal growth spurt at the time of SCI have the highest rate of scoliosis, approaching 100%.²¹ The pattern of curvature in post-SCI scoliosis is similar to that observed in other cases of neuromuscular scoliosis.

PATTERNS OF INJURY AND TREATMENT RECOMMENDATIONS

Atlanto-Occipital Dissociation

Historically, these injuries were almost universally fatal because of high cervical spinal cord/brainstem injury and resultant respiratory arrest. Hypoxia secondary to brainstem or high cervical cord injury also portends a poor prognosis. With modern Advanced Trauma Life Support protocols, specifically on-site intubation, cervical spine immobilization, and ventilator support, more children are surviving these injuries. A 2003 review of the literature found evidence of 41 children surviving for >48 hours after recognized AOD. Despite the severity of these injuries, there are case reports of preservation of neurological function after AOD.^{22,23}

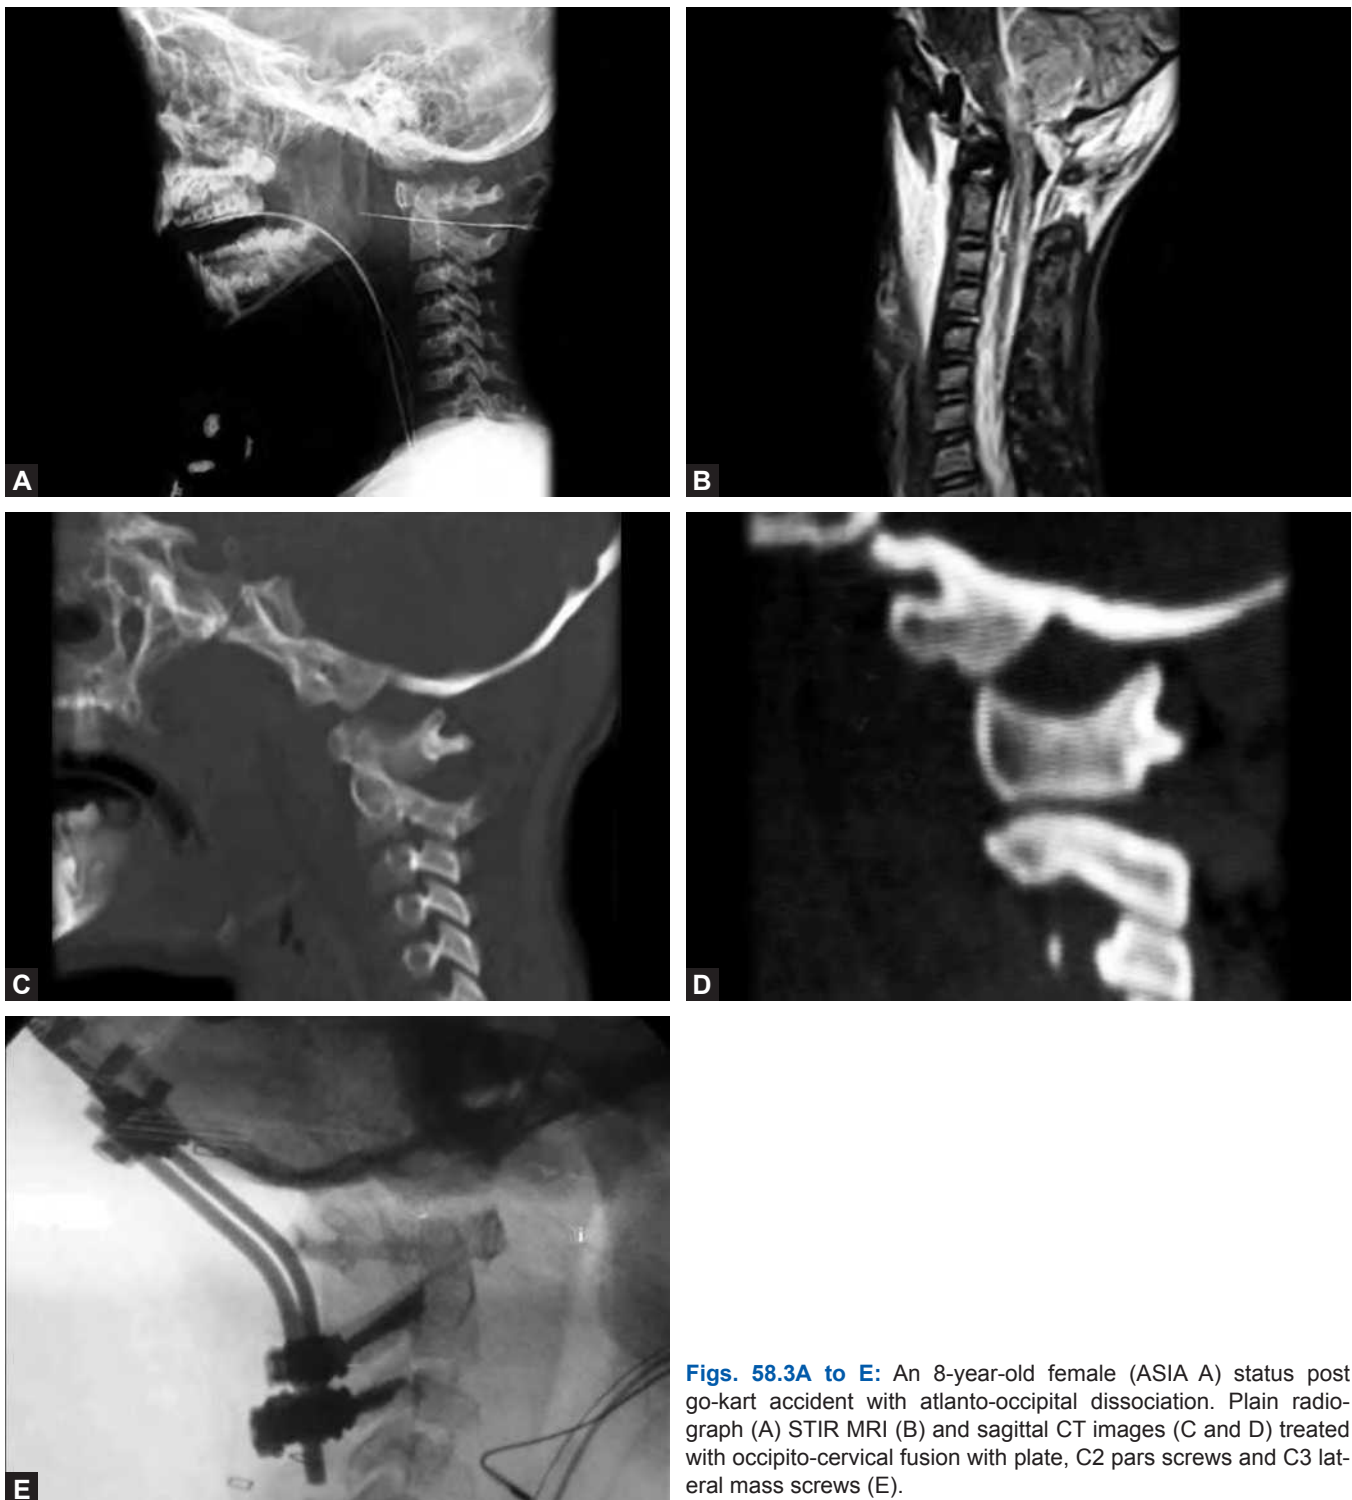

Figs. 58.2A to C: A 4-year-old male (ASIA A) ejected from car in unrestrained car seat. Patient noted to have respiratory arrest in the field. Sagittal (A) and parasagittal CT (B) and STIR MRI (C) images demonstrating atlanto-occipital dislocation. Note normal physis of odontoid (*) in figure A.

The first step in treating a child with AOD is to recognize the injury. This requires a high index of suspicion, as up to one third of children with AOD may not be identified during initial evaluation;²⁴ this number may be even greater than that in adults.²⁵ Children with AOD are usually the victims of high-energy motor vehicle accidents (Figs. 58.2 and 58.3). Lack of respiratory drive is a clue to high cervical spine injury, although the patients are commonly intubated on scene. Concomitant head injury is common and may obscure the diagnosis. Cranial nerve palsies, especially involving VI, and IX–XII may be seen.^{24,25}

The use of traction is contraindicated and a properly sized rigid pediatric cervical collar is essential, and must be applied carefully so that no distractive forces are applied to the spine. If AOD is recognized in a pediatric trauma patient, the authors recommend immediate reassessment of cervical spine immobilization. The use of specialized pediatric backboards with a recess to accommodate the

proportionally larger occiput of a child prevents relative flexion of the upper cervical spine (Fig. 58.4). Taping the child's head to the backboard with sandbags used as bolsters to immobilize the cervical spine may be the most efficacious way to ensure the head and cervical spine are immobilized until a halo thoracic vest can be placed. The use of methylprednisolone in SCI continues to be controversial. The National Acute Spinal Cord Injury Study trials specifically excluded patients younger than 14 from their studies.

When electing to pursue halo vest treatment in children, the placement of the vest is different than adults. More pins are typically used and they are tightened to a lower torque. For children aged 3 and younger, the use of up to 12 pins, tightened to 2 inch-pounds of torque has been described.²⁶ For children aged 4–10 years, the authors recommend the use of six to eight pins tightened to 2 inch-pounds of torque. For patients between 10 and 15 years, the authors recommend

Figs. 58.3A to E: An 8-year-old female (ASIA A) status post go-kart accident with atlanto-occipital dissociation. Plain radiograph (A) STIR MRI (B) and sagittal CT images (C and D) treated with occipito-cervical fusion with plate, C2 pars screws and C3 lateral mass screws (E).

four to six pins tightened to 6 inch-pounds, and for patients 15 years and older, four pins tightened to 8 inch-pounds are used. The authors strongly recommend placement of a halo

vest in the operating room with sedation, as well as having a C-arm available and positioned so that lateral radiographs may be taken to evaluate for reduction.¹¹

Fig. 58.4: Hyperflexion of pediatric cervical spine secondary to improper use of backboard accentuating deformity of atlanto-axial dislocation (*).

Children with AOD are typically the victims of polytrauma, and close coordination between the pediatric intensivists, general surgeons, neurosurgeons, and spine surgeons is essential. As mentioned previously, prognosis is guarded in these patients, particularly those with anoxic brain injury. Before proceeding with surgery, a realistic discussion must be had between all involved teams and the family, who will typically push for any intervention in the frequently unrealistic hope that it may cure the child.

Definitive surgical stabilization of AOD in the pediatric patient requires a fine-cut computed tomography (CT) (1 mm slices) scan of the cranial-cervical junction. In children younger than 12 months, an iliac-crest autograft onlay technique is recommended.²⁷ This consists of decorication of the occiput, as well as the C1 and the C2 lamina with wiring of strips of autogenous iliac-crest bone graft via drill holes in the cranium and sublaminar wires at C1 and C2 (Figs. 58.5A and B). A key technique to passing sublaminar wires is to use the blunt end of a 0-Vicryl on a tapered, e.g. “SH” needle (Ethicon, Somerville, NJ) to preliminarily pass a strand of suture behind the lamina. This can then be gently flossed back and forth to create a tract for the wire itself.²⁸ Because onlay wiring provides little inherent stability, these patients are kept in a halo-thoracic vest or a Minerva cast for a minimum of 3 months postoperatively, ideally until definitive fusion is seen. In children older than 12 months, rigid internal fixation of the OCC is frequently possible. Anderson et al. have published a useful algorithm for the stabilization of the

Figs. 58.5A and B: A 17-year-old male (ASIA E) with Type II odontoid fracture, preoperative lateral X-ray (A) treated with C1-2 transarticular screw fixation and sublaminar wiring (B).

craniovertebral junction in pediatric patients.²⁹ The first goal is to evaluate for the placement of C1-C2 transarticular screws to act as an anchor for either a titanium loop or an occipital plate. Some authors have shown that up to 89% of children may be candidates for C1-C2 transarticular screw placement.³⁰ Careful evaluation of the course of the vertebral artery is essential, and vertebral artery injury is known to occur in even the most experienced hands. 3.5 mm screws are recommended for patients younger than 4 years of age, and 4.0 mm screws for those older than 4.³¹ After successful placement of a C1-C2 transarticular screw, a looped titanium rod can then be secured to the screws via a set-plug and to the occiput via wires; screws, or an occipital plate, may be used in older children. Other potential anchoring sites include C2 pars screws, C2 laminar screws, and subaxial lateral mass screws.²⁹ Halo immobilization may be unnecessary in patients with rigid internal fixed AOD,²⁹ although the authors would recommend a cervical collar be continued until evidence of fusion is seen.

Fractures of the Atlas

Fractures of the atlas are relatively rare in the pediatric population.⁵ Moreover, because these fractures are generally associated with an increase in canal volume, they are rarely associated with SCI. Fractures through the synchondroses of the atlas have also been described.³² In general, these patients can be immobilized in a halo vest, as described above, while their fracture heals.

Atlanto-Axial Instability

Like, AOD, traumatic atlanto-axial instability (AAI) results from the disruption of the ligamentous stabilizers of the OCC as a result of high-energy trauma. This injury is more commonly observed in children younger than 11 years of age, most likely because of the proportionally larger size of the head in these patients.⁵ That children have greater motion at the C1–C2 articulation than adults is well recognized. Up to 4 mm of motion in the anterior atlanto-dens interval on flexion–extension radiographs is normal.³³ This increased ligamentous laxity may confound diagnosis based on plain radiographs or CT scans, although this is less of an issue with the widespread use of MRI.

Spinal cord injury following traumatic AAI should be approached in a similar manner to AOD. These children are also commonly multiply injured, intubated on scene, and may have hypoxic brain injury secondary to respiratory arrest from their high cervical SCI. Temporary halo thoracic fixation of these injuries is recommended to stabilize the spine during the initial evaluation and treatment of the patient.

Definitive surgical stabilization of traumatic AAI in pediatric patients also follows a similar algorithm to AOD. For children younger than 1 year of age, although the use of C1–C2 transarticular screws has been reported,²⁹ a critical evaluation of the course of the vertebral artery must be done prior to surgery. If there is any doubt about the feasibility of a transarticular screw, we recommend placement of onlay iliac-crest bone graft with posterior wiring of C1–C2 with postoperative halo thoracic immobilization. In children older than 1 year of age, a Brooks sublaminar technique with bone grafting is also useful. C1–C2 transarticular screws are also feasible and in one large study have a reported 100% fusion rate.³¹ However, the incidence of vertebral artery injury in this series was two of 67 (3%).

Atlanto-axial instability associated with os odontoideum is also a relative indication for C1–C2 fusion, particularly in the setting of cervical cord neurapraxia (CCN) or cervical SCI. Patients with os odontoideum may have significant instability noted on flexion–extension radiographs, up to 1.3 cm.³⁴ To prevent recurrent CCN or possibly SCI, the authors recommend C1–C2 fusion for patients presenting with CCN and os odontoideum. Transarticular screws are the fixation technique of choice and have high reported fusion rates.³¹

Odontoid Process Fractures

Fractures of the odontoid process are relatively rare in younger children; however, they become more common in children older than 12 years of age.⁵ Pediatric odontoid fractures are infrequently associated with SCI.³⁵ In young patients, the odontoid fracture can typically be reduced either with hyperextension of the neck, manipulation under anesthesia or traction, or halo thoracic immobilization or Minerva casting with very high reported rates of union.³⁵

Odontoid process fractures in adolescents follow similar patterns of injury as found in adults. The vast majority of these can be treated with halo thoracic immobilization while the fracture heals. Although their study consisted primarily of adults, the findings of Koivikko et al. regarding the increased rates of nonunion following conservative management of odontoid fractures in patients with fracture gap >1 mm, posterior displacement >5 mm, and posterior redisplacement >2 mm are also illuminating in the treatment of adolescent odontoid fractures (*see* Figs. 58.5A and B).³⁶

Subaxial Cervical Spine Injuries

As mentioned previously, injuries to the subaxial cervical spine are less common, particularly in younger children. However, in children 11 years and older, there is a significant increase in the occurrence of fractures and fracture–dislocations of the subaxial cervical spine.⁵ Approximately, half of these injuries may be associated with an SCI.³⁷

Injury patterns are generally similar to those seen in adults and include compression fractures, burst fractures, facet dislocations and fracture–dislocations. Unique to the pediatric population are fractures of the physeal end plates,³⁸ which may be highly unstable, and are commonly associated with SCI.³⁷

For children with subaxial cervical spine injuries, initial treatment is guided at reducing any deformity to realign the spinal canal and relieve compression on the spinal cord. The authors recommend halo ring be placed in the operating room, as described previously, and traction applied in a gentle manner to achieve reduction. Commonly, 3 months of halo thoracic fixation may represent definitive treatment, particularly for simple facet dislocations and burst fractures. Fracture–dislocations are unstable injuries that commonly require operative treatment.

Figs. 58.6A to C: Lateral cervical spine X-ray (A) and sagittal STIR MRI (B) image demonstrating severe congenital cervical spinal stenosis and spinal cord contusion in a 17-year-old male who suffered a 15 minutes episode of cervical cord neuropraxia while playing football. Postoperative lateral X-ray after C3–4 ACDF (C).

There are multiple options for stabilization of the cervical spine in the pediatric population, including both anterior plating and posterior lateral mass screw fixation, all with high rates of arthrodesis (Figs. 58.6A to C).³⁹ Some concern exists regarding anterior fusion, which may prevent subsequent longitudinal growth of the spine in pediatric patients,³ although this has not been well studied in the literature. Successful posterior lateral mass screw fixation has been described in children as young as 6 years of age.⁴⁰ Other options for treatment include traditional onlay bone graft and spinous process or sublaminar wiring with postoperative halothoracic immobilization. The relation of timing to surgical decompression to final neurological recovery of subaxial cervical SCI has not been well studied. A recent prospective, randomized, controlled trial specifically excluded children younger than 16 years of age; however, the findings of the STASCIS trial that early decompression (<24 hours) may improve outcomes can help guide the treatment of cervical SCI in children as well.⁴¹

Thoracic, Thoracolumbar, and Lumbar Spine Injuries

Compression and burst fractures are commonly observed in children as a result of vehicular accidents, sport, and falls. The vast majority of these are not associated with SCI and may be treated with an external orthosis or cast.¹⁹ In our experience, patients presenting with 25° of kyphosis

or more, particularly when this is noted on supine CT scanning, should be watched closely for the development of progressive kyphosis.⁴² Progressive kyphosis resulting from an incompetent anterior column or a torn posterior ligamentous complex is a relative indication for surgical stabilization, which may be done via an anterior, posterior, or combined approach depending on the surgeon's preference and on the exact injury pattern. Typically, patients older than 12 years of age are treated in a manner similar to an adult.

Pediatric thoracic spinal fractures associated with SCI are a result of a high-energy injury and commonly require surgical stabilization due to their inherent instability. Physical examination may reveal a posterior step off, spinous process widening, an interspinous defect or subcutaneous ecchymosis, all of which are clues to a severe injury (Figs. 58.7A to C). Fracture-dislocations are generally reduced with hook or pedicle screw constructs. The widespread use and recognized safety of pedicle screws in adolescents and even in younger children for scoliosis⁴³ has led many practitioners to use such constructs for spinal trauma as well. Despite animal data suggesting that instrumentation across the neurocentral synchondrosis may impede the growth of the spinal canal,⁴⁴ this has not been observed clinically in children as young as 1 year of age undergoing transpedicular screw placement.⁴⁵ Furthermore, transpedicular fixation may help prevent development of crankshaft deformity following thoracic spinal fusion in a canine model.⁴⁶

Figs. 58.7A to C: A 16-year-old female status post rollover MVA with L1 burst fracture (ASIA B), sagittal CT (A) and STIR MIR (B) treated with anterior corpectomy and posterior fusion (C). Patient was ASIA E at 3-month follow-up.

The spectrum of flexion-distraction or “seat belt” injuries in children deserves special consideration (Figs. 58.8A to F). These injuries almost exclusively occur following rapid deceleration in motor vehicle accidents in children restrained by either lap or three-point harnesses. Hyperflexion of the spine occurs with the instantaneous axis of rotation located anterior to the vertebral bodies, resulting in distraction across all three columns of the spine. Flexion-distraction injuries are commonly associated with intra-abdominal injuries, particularly hollow viscus perforation, and even aortic occlusion.^{47,48} Seat belt injuries differ from true Chance fractures, which were originally described as only an osseous injury.⁴⁹

Treatment of flexion-distraction injuries is dependent on the pattern of injury. True Chance fractures may be treated in younger children, depending on their body habitus and weight, with a hyperextension cast or external orthosis. We have found it easier to place the cast or mold the brace with the patient under general anesthesia in the prone position. These ligamentous or combined osseoligamentous injuries are more easily treated with short-segment compression hook constructs or pedicle screw fixation. A fusion may or may not be included and the necessity of a formal fusion is controversial since most of these patients fuse spontaneously. In patients treated with bracing or casting, progressive kyphosis is an indication for posterior instrumentation with or without fusion. Patients with flexion-distraction injuries undergoing surgery may have less final kyphosis than those treated nonoperatively.⁵⁰

Post-traumatic Spinal Deformity

As mentioned previously, the incidence of post-SCI spinal deformity may be as high as 100% in patients who suffer injury before their adolescent growth spurt.²¹ These patients should be carefully monitored for the development of scoliosis, particularly during periods of rapid trunk growth: until age 12 in females and 14 in males (Figs. 58.9A and B).

Bracing should begin immediately when any curvature is detected. Curves that are braced before they reach 10° have some hope of being successfully managed in a brace, while surgery is considered for patients presenting with curves >20°. ⁵¹ The pattern of curvature in post-SCI scoliosis is similar to that seen in neuromuscular scoliosis. The goal of treatment should be realignment of the spinal column to improve sitting balance. Fusion is almost always carried to the pelvis.

KEY POINTS

- Patterns of spinal trauma are different in children younger than 10 years of age, while older children tend to mimic fracture patterns seen in adults.
- A high index of suspicion for injuries to the occipital-cervical complex is critical in the treatment of trauma victims younger than 4 years of age, particularly those presenting with respiratory arrest and involved in motor vehicle accidents.

Figs. 58.8A to F: A 17-year-old female (ASIA E) status post 4-wheeler accident versus tree with L1 flexion distraction injuries. Lateral X-ray (A), sagittal CT scan (B), sagittal STIR MRI (C and D) images demonstrating disruption of posterior ligamentous complex, and rolling of interspinous ligament (arrow). Intraoperative photograph (E) demonstrating fascial rent and torn posterior ligamentous complex. Postoperative lateral X-ray (F).

Figs. 58.9A and B: Six months postoperative composite radiograph (A), and 6 years postoperative radiograph (B) demonstrating post-SCI scoliosis developing 6 years after complete SCI at mid-thoracic level.

- Cervical instrumentation is a useful and safe technique for treating injuries to the upper cervical spine, even in very young children older than 1 year.
- Younger children involved in motor vehicle accidents have unique flexion-distraction injuries due to seat belts and commonly present with serious intra-abdominal and vascular injuries.
- Scoliosis following spinal cord injury is common, particularly in skeletally immature patients, who should be observed until they finish growing.

INTRODUCTION

Penetrating spinal cord injury (SCI) comprises a distinctive subset of spinal injury that deserves special consideration. Unfortunately, the most common reason for penetrating SCI is personal violence.¹ Gunshot wounds and stabbings account for the greatest proportion of penetrating SCI, followed by injuries from falls onto sharp objects and industrial accidents that may or may not involve projectiles or shrapnel.²⁻⁶

Penetrating SCI resulting from personal violence disproportionately affects young males between 15 and 35 years of age.⁴ In addition, industrial accidents and high energy falls also tend to affect the working (manual laborer) population. Spinal cord injury that occurs on the battlefield and in a military setting also disproportionately affects the young adult male population.⁷ Battlefield injuries inflict devastating consequences both physically and from a public health perspective.⁷ The yearly cost of care for SCI patients exceeds 100 million dollars.⁸ With only 35–40% of all SCI patients obtaining any form of paid employment, factors such as lost productivity, along with disability service care must also be considered as part of the tremendous burden and cost of these injuries.^{9,10}

Throughout this chapter, penetrating SCIs will be considered in light of the unique mechanisms that

generate them. The resultant pathophysiology, unique characteristics, injury patterns, and associated injuries will be addressed. The three main injury mechanisms (gunshot wound, stabbing, and miscellaneous) will be discussed, as each mechanism carries with it unique considerations for evaluation of the primary injury as well as associated injuries. Treatment regimens are tailored accordingly. Special considerations such as increased potential for infection and resultant treatment decisions will be identified. Patient evaluation including assessment of neurologic status, imaging, and assessment of stability, and prognosis will be taken into consideration in the context of penetrating injuries to the spine. Finally, operative and nonoperative treatments will be discussed.

PATHOPHYSIOLOGY

Gunshot Wounds

Gunshot injuries to the spine should be understood in the context of their pertinent ballistics. The energy imparted by a gunshot missile has important implications as to the tissue damage, associated injuries, and treatment decisions. The ballistics of firearms determines the energy imparted by a projectile on the injured spine and surrounding tissues. Kinetic energy (KE) is calculated

according to the equation $KE = 1/2 mv^2$ (m = mass and v = velocity). Based on this physical principle, increases in velocity impart an exponential increase in KE, which transfers into a significant increase in tissue destruction.⁴ Generally speaking, guns with muzzle velocity below 2,000 ft/s are considered “low velocity” (low energy) and over 2,000 ft/s are considered “high velocity” (high energy). There is some gray zone for interpretation between 1,000 and 3,000 ft/s.⁴ Low-velocity weapons tend to fall in the category of civilian style guns such as pistols, whereas military type assault weapons and some long-range hunting rifles are considered high velocity. Shotguns impart a low velocity but high energy due to the large mass of the pellets or slug that is delivered. Also the wounds that are generated often contain wadding, which is a packing around the shot that is considered a contaminant.⁴ Thus, shotgun wounds are considered to have high potential for infection and necessitate aggressive early debridement. Since both low- and high- velocity guns exist in both civilian and military conflicts, it is important to identify the particular weapon used in each injury, as it will help in focusing treatment.

The “mass” component of $1/2 mv^2$ imparted in gunshot wounds is important. However, tissue destruction is based on total energy delivered to the target (the injured human). This can vary substantially based on whether the bullet passes through the target or comes to a complete stop inside the target. Bullets that are jacketed tend to pass through targets, whereas bullets that yaw (wobble) enter the target at an angle that presents a greater cross-sectional area and, thus, make a larger cavity. Bullet shape and material also affect the behavior. Hollow-tipped or split-end bullets (“dum-dum rounds”) tend to expand on impact. Softer materials like lead are more likely to expand or fragment as well. All of these characteristics combine to leave a larger destructive zone of injury. Thus, more energy is imparted and greater damage is created. The shape, characteristics and material of a bullet substantially affect its flight and energy delivered. The material of a bullet (typically lead) also carries with it a potential to cause toxic effects. Nevertheless, it is rare that bullets lodged in the spine need to be removed due to lead toxicity.⁴ Serum lead levels and bone marrow biopsies can be performed to guide treatment when this is a concern. Copper has also been shown to have neurotoxic effects when adjacent to neural tissue in the spine.¹¹ However, it is not typically possible to determine bullet composition clinically. If the patient is neurologically intact, the damage of

removing fragments, when toxicity has not been demonstrated would likely not be worth the risk.

Ultimately, the tissue damage imparted by gunshot missiles can come from three mechanisms: (1) direct (missile contact) tissue destruction, (2) pressure or shockwave (concussive effect), and (3) temporary cavitation.¹² Concussive effects cause neurologic damage as missiles pass near, but not through the neural tissues. Thus, it may not be apparent based on visualized tissue destruction, but this type of injury can cause SCI. High-velocity firearms such as those used in the military are more likely to generate such effects.

Unfortunately, the initial injury sustained by the projectile is not always the final insult. Farrugia et al. reviewed the literature along with their own case presentation of reported bullet migration in the spinal canal. They concluded that bullet migration within the spinal canal is possible and may occasionally cause neurologic harm.¹³ Bullets may initially ricochet and thus do not always take a straight-line trajectory from the entrance wound. Also the gravity may influence passive migration of projectiles within the canal.

■ STABBING AND MISCELLANEOUS (NONMISSILE MECHANISMS)

Stabbing is the most common penetrating mechanism to cause SCI other than gunshots. Since other miscellaneous mechanisms are rare and their inherent characteristics are similar to stabbing with sharp objects, they will be discussed together.

A 12-year series of SCI resulting from stabbings was reported by Saeidiborjeni et al.¹⁴ Cervical and thoracic locations were involved in about 80% of injuries, split almost equally in prevalence.¹⁴ About 43% of injuries were sensory and motor complete [American Spinal Injury Association (ASIA) A].¹⁴ A stabbing or nonprojectile mechanism for penetrating SCI may also damage the spinal cord directly or indirectly. The injury may range from minor epidural involvement to complete spinal cord transection. “Indirect” injury may also result from the blunt force of the penetrating object causing contusion of the spinal cord and/or impact with the bony canal. With stabbing injuries, a “cord hemisection” type injury is more common because of the shape of the bony anatomy.¹⁵ The path of least resistance for the penetrating object (typically a knife) appears to be in the gutter between the transverse process and spinous process. The caudally and sagittally oriented

Fig. 59.1: A sharp object, which is placed adjacent to the spinous process demonstrating a typical stabbing (caudal-cephalad) trajectory. Entrance to the spinal canal is often lateralized due to the blocking effect of the spinous process over the midline and shingling of the posterior elements.

Fig. 59.2: A sharp object oriented to illustrate a more lateralized trajectory. This demonstrates how a side penetrating injury may enter the canal through the foramen and cause spinal cord injury. The extent of penetration will determine the degree of injury. One can visualize how a cord hemisection or even complete transection is possible.

spinous process provides a block to penetration across the midline (Fig. 59.1).¹⁶ Thus, the characteristic Brown-Sequard syndrome of ipsilateral motor and proprioceptive loss with contralateral pain and temperature dysfunction occurs. This scenario holds true for a posterior stabbing or fall on the back (especially to the side) that causes an impaling wound. A laterally directed penetrating object can enter the canal through the foramen, and cause nerve root and spinal cord damage (Fig. 59.2). The extent of penetration will determine the degree of neural injury. One can visualize how a cord hemisection or even complete transaction is possible. Penetrating objects can approach the spine and neural elements from 360° along the X-Y axis and at any angle from above or below the Z axis; nevertheless, the bony structures play a considerable role in limiting neural tissue damage.

PATIENT PRESENTATION

Just as with any trauma evaluation, the patient with penetrating SCI should be evaluated according to the principles outlined by Advanced Trauma Life Support. Similar to blunt trauma, an algorithmic approach to penetrating trauma based on the prioritization of airway management, breathing, and circulatory support (ABCs) is the key to optimizing survival. Penetrating injuries to the chest and abdomen are more likely to result in mortality via exsanguination or hypoxemia.¹⁷ The patient who sustains

penetrating spinal injury should be thoroughly evaluated to rule out associated or concomitant injuries. It stands to reason that adjacent structures proximal to the affected spinal anatomy should be closely evaluated. Blair et al. reviewed an 8-year series of penetrating spinal injuries in military personnel. For all comers, concomitant abdominal injuries were the most common (36%) followed by thoracic injuries (30%).⁷

CONCOMITANT INJURIES OF THE CERVICAL REGION

Penetrating injuries to the cervical spine may be more likely to have airway, visceral, and vascular injuries. The surgeon should recognize a few special considerations when evaluating patients who have sustained gunshot injuries. The majority of civilian (low velocity) gunshot wounds to the spine are stable injuries. Evaluation and treatment of life-threatening injuries should not be delayed to obtain C-spine clearance.⁴ Cervical fractures from gunshot wounds tend to be mechanically stable.^{18,19} Appropriate imaging should be obtained in order to make this determination; however, inline stabilization can be used if airway and vascular management is necessary on an immediate basis. If examination of the neck reveals pulsatile bleeding or expansile hematoma, then the carotid or vertebral artery injury should be suspected and appropriate vascular consultation should be obtained in

a timely fashion.²⁰ A high suspicion should be maintained for detecting tracheal or hypopharyngeal injury. Either may lead to early mediastinal infection.

■ CONCOMITANT INJURIES OF THE THORACIC REGION

Patients with thoracic spine injuries are more likely to have sustained pleural injuries and life-threatening vascular injuries. Auscultation of the chest is the quickest and most reliable way to rapidly assess for hemothorax or pneumothorax.⁴ Cardiac perforation or tamponade is also possible, which reinforces the need to prioritize the care of patients with penetrating spinal injuries in the same fashion as any trauma patient (“ABCs” first).

■ CONCOMITANT INJURIES OF THE LUMBAR SPINE

Patients with lumbar penetrating mechanisms have a high likelihood of associated contaminating visceral injury. These injuries have a high risk of infection and peritonitis.^{21,22} Wounds in this region must be considered to have viscus injury until proven otherwise. Also the presence of great vessel injuries must be ruled out. Typically, computed tomography (CT) scan and abdominal ultrasound are the first imaging techniques to be employed. Computed tomography angiogram or endoscopic examination can also be utilized.

Once the patient is stabilized, he or she should be evaluated for neurologic dysfunction and spinal stability. The cervical spine should be immobilized with a rigid collar until imaging is completed.⁴ The spine should be completely inspected and palpated while the patient is log-rolled. Bullet entrance and exit wounds should be identified and marked with a radiopaque marker such as a paper clip taped to the skin. Superficial debridement of clothing or surface debris and bullet fragments is recommended. But it is not necessarily recommended that wounds be deeply probed or closed. A complete neurologic examination is mandatory. Within the context of acute spinal trauma, the neurologic examination is performed in accordance with the International Standards for the Neurologic Classification of Spinal Cord Injury, formerly the ASIA standards.^{23,24} Patients who suffer SCI from a penetrating injury are much more likely to suffer complete (ASIA A) injuries.^{1,4} The authors have found it very useful to standardize communication by adopting the ASIA standardized neurologic

assessment form into chart documentation. This helps to sustain a standard of communication and reminds clinicians of all the important elements necessary for a thorough examination. This also facilitates scientific and clinical follow-up. Completeness of injury is related to the anatomic region. Patients who have sustained gunshots to the spine with incomplete injuries and patients with injuries in the thoracolumbar region have the greatest improvement in motor function. Approximately 25% of individuals are able to ambulate 1 year after injury.²⁵ Waters et al. reviewed a large series of SCIs resulting from stab wounds. Thirty-two patients were evaluated. About 63% presented with motor incomplete lesions. Half of the patients with motor incomplete lesions had asymmetrical motor patterns indicative of a Brown-Sequard syndrome. Although the percentage of patients sustaining an incomplete SCI injury following a stab injury to the spine is higher than the percentage of incomplete lesions associated with other etiologies, the amount of motor recovery when controlling for level and completeness of injury is no greater than that previously reported for other etiologies.²⁶

Hypovolemic shock should clearly be differentiated from neurogenic shock. Neurogenic shock typically occurs due to SCI rostral to T4 and upon presentation to an *emergency department* is only seen in 20% of cases.²⁷ A distinct physiologic condition exists in which the heart rate is typically <80 and the systolic blood pressure is <100. This occurs because of an overpowering of vagal output combined with a physiologic loss of sympathetic function. Once a patient is adequately volume resuscitated, neurogenic shock should be managed with pressor support. Occasionally, cardiac pacing is required.

■ IMAGING

The initial imaging of choice for patients with penetrating injuries to the spine is plain X-ray. The general location of the object (missile, blade or foreign object) and the presence, number, and location of fragments can be deduced on anteroposterior and lateral X-rays. The authors prefer marking the entry and exit wounds (in the case of projectile injury) with a radiopaque marker that is readily identifiable such as a paper clip. The use of electrocardiographic markers or other clinically common objects may be difficult to discern if they happen to be present for other purposes. By identifying the entry and exit sites, a relative path of travel can be ascertained.

Once a spinal injury is identified and the patient is physiologically stable (or if injury is suspected but cannot be fully ascertained by plain film), the CT scan should be

obtained. Plain film imaging will help guide the region of interest to target for CT scan. Thin-cut (1–3 mm) CT scan is preferred. It allows three-dimensional visualization of the missile(s) and establishes the relationship between them and the anatomic structures such as bone, disk, neural elements, and vascular structures. If vascular or visceral injury is suspected, various contrast media can aid in visualizing these structures as well. Computed tomography has the potential to cast significant artifact from metallic objects. Therefore, magnetic resonance imaging (MRI) may be a useful adjunct when anatomy is obscured.

The choice of MRI must be taken in context with the desired utility and risks. If the penetrating injury is from a bullet, it is unlikely that migration of the embedded fragments will occur and thus it is generally considered safe to perform MRI.⁴ However, if the object is composed of a highly ferromagnetic substance such as a steel wire, knife blade or nail from a nail gun, then greater caution should be exercised. The authors recommend MRI when neurologic injury is present but cannot be explained by CT imaging. Also MRI may be a helpful addition in those cases where surgical planning cannot be adequately performed with only a CT. Soft tissue and neural element visualization is obviously enhanced with MRI and, thus, can be seen as a complimentary imaging modality to CT in the case of gunshot injury. In the case of stabbings (in which the penetrating foreign object is not retained), MRI has demonstrated utility. MRI is useful in identifying the stabbing tract (high signal characteristics).²⁸ In the case of neurologic injury, there is typically a spinal cord contusion, which is demonstrated by high signal, representing intraparenchymal spinal cord edema.²⁸ MRI characteristics after stabbings can help confirm the anatomic location and correlate it with neurologic level. Furthermore, it may help to prognosticate neurologic recovery since MRI injury characteristics have been shown to correlate with prognosis after SCI.^{29,30}

SPECIAL CONSIDERATIONS

The imaging or clinical protocols for clearing the cervical spine in the case of cranial gunshot wounds are of little utility due to the relative lack of evidence.^{4,18,31,32} Gunshots to the mid-face and orbits have a much higher likelihood of cervical injury, and thus a high suspicion should be maintained.^{4,33}

When performing MRI, it should be noted that the decision to do so for penetrating injury should be made

on a case-by-case basis. The most common complaint in the case of retained bullet fragments is that the patient experiences a sense of heating in the wound, which has the potential for severe discomfort.⁴

Nonoperative Treatment

Nonoperative treatment for penetrating SCI can take the form of medical treatment and external spinal stabilization. Medical treatment is typically meant to prevent infection. The rationale for nonoperative treatment for the spinal injury is based on assessment of spinal stability, the prognosis, and the mechanism of neurologic injury.

Antibiotic Treatment

All patients with penetrating injury to the spine should be considered for tetanus prophylaxis. If there is any doubt of a patient's status, he or she should have tetanus immunization administered in the emergency department. Antibiotic prophylaxis for all penetrating spinal injuries is recommended. The choice of agent and duration is guided by the mechanism of injury and any associated internal injuries such as gastrointestinal perforation. For uncomplicated gunshots to the spine that do not involve gastrointestinal injuries, 48–72 hours of broad-spectrum antibiotic coverage is typically recommended.⁴ Penetrating SCI with associated gastrointestinal injury puts the patient at significantly higher risk of infection.³⁴

There are no randomized controlled trials or even well-designed cohort trials that have been designed specifically to answer the question of duration of antibiotic treatment in patients with penetrating SCI and gastrointestinal perforation. It is well accepted that broad-spectrum coverage should be utilized.⁴ Duration of intravenous (IV) antibiotic treatment appears to be up for some debate. Lin et al. retrospectively studied 29 patients with gunshot injuries to the spine. Of the 21 patients with a parenchymal and/or noncolonic viscous injury, 17 (77%) were treated with IV antibiotics for a minimum of 5 days. The remainder received treatment for a maximum of 48 hours. All eight patients with colonic injuries had a minimum of 5 days of antibiotic treatment. No patient developed spinal infection. The authors concluded that patients who sustained a transperitoneal low-velocity gunshot wound to their spine should be treated with a minimum of 5 days of appropriate antibiotic treatment.³⁴ Infection rates are highest with colonic perforation, especially when a projectile enters the colon before entering the spine.³⁵

Noncolonic perforations have not been shown to pose a significant risk for spinal infection (though peritonitis for small intestine and mediastinitis for esophageal injury, remain a concern).^{4,35} Roffi et al. retrospectively reviewed patients with gunshots to the spine who also sustained transcolonic, small intestine, and stomach perforations. They concluded that an extended course of broad-spectrum antibiotics (at least 7 days) combined with bedrest appeared to significantly reduce the risk of spinal or paraspinal infection.²²

Early bullet removal did not appear to be a significant factor in the prevention of infection.²² Kumar et al. came to a similar conclusion and summarized “Because the magnitude of bacterial colonization of the vertebrae after colonic injury may not be high, a nonoperative approach to treatment of abdominal viscus injuries is appropriate in patients with gunshot wounds to the spine. Broad-spectrum antibiotic coverage for at least seven days appears to be effective in preventing spinal infection, but colonic injuries are associated with an increased incidence of intra-abdominal abscess and peritonitis.”²¹

There are no studies that prove the efficacy of spinal debridement to prevent infection. In fact, the opposite appears true. In a cohort study comparing groups of surgical versus nonsurgical treatment of spine patients with transgastrointestinal gunshot wounds, a significantly higher rate of spinal infection was noted for surgically treated patients than nonsurgical patients.³⁶ There is a significantly higher rate of spinal and wound infections with transgastrointestinal gunshot wounds to the spine. Injuries that involve the colon put patients at risk for the development of spine infections after spinal surgery.³⁶ Quigley stated that randomized controlled trials are necessary for the development of a specific protocol for IV antibiotic therapy in the setting of transgastrointestinal gunshot wounds to the spine.³⁶

■ STEROID TREATMENT

Well-designed studies have been performed on patients with penetrating SCI to investigate the utility of high-dose steroids such as methylprednisolone. It has been established that steroid therapy for penetrating SCI may actually impair recovery of neurologic function.³⁷ It has also been shown that nonspinal complications such as infection and organ failure occur at a higher rate when steroids are administered.³⁸ Patients who sustain penetrating SCI

should not be treated with steroids because the efficacy of such treatment has not been proven in a controlled study.

Nonoperative Spinal Stabilization

The majority of penetrating spinal injuries are considered mechanically stable.^{4,7,12,39} Bono and Heary identify the challenges in applying historically accepted methods/classifications for spinal instability to gunshot injuries.⁴ Most stability classifications describe mechanisms of injury for blunt trauma, in which the patient is rapidly decelerating. In the case of penetrating injury, the projectile or foreign object such as a blade is traveling at a high velocity relative to the patient and rapidly decelerates. This creates a scenario whereby the penetrating object creates damage primarily in its direct path, the exception being the concussive and cavitation effects that bullets can have (which is exponentially proportional to the muzzle velocity of the projectile). Assessment of stability should be done on a case-by-case basis.

Radiographic factors such as subluxation, dislocation, acute kyphosis, and loss of key bony elements will help the clinician identify an injury that is unlikely to heal in an acceptable alignment for good mechanical function and neural protection. The concept of stability is not an “all or none” phenomenon and should be considered as a spectrum from stable, to potentially unstable, to frank instability. Likewise instability is not necessarily always identifiable with static imaging at the time of initial evaluation. Upright imaging and delayed flexion–extension X-rays (along with clinical assessment of pain) may be valuable in helping the clinician identify the “character” and “behavior” of the injury. Until these images are obtained, the patient’s injury can be braced for protection. The cervical spine is a region that needs special consideration. Unlike with blunt trauma, where radiographic criteria are relatively well accepted, any abnormal angulation or subluxation is considered suspicious for instability; thus, it has been recommended that surgeons err on the side of caution in these circumstances and treat with surgical stabilization.⁴

■ OPERATIVE TREATMENT

One of the key considerations in the evaluation and planning for surgical treatment of penetrating SCI is the determination of the goals of surgery. Surgical treatment goals include re-establishing spinal stability, obtaining neurologic decompression, wound debridement, and the

Table 59.1: Role for surgery.

Irrigation and debridement
Toxicity prevention
Removal of object/missile
Spinal stabilization
Neurologic decompression

removal of retained objects to prevent migration or toxicity (Table 59.1).

Once it has been determined that surgery is required, a key factor for consideration is the importance of timing of surgical intervention. Rapid surgical intervention is typically only warranted in patients with progressive neurologic deterioration, as documented by serial examination. This may occur by expanding hematoma or migration of retained foreign material. Shotgun and explosive wounds also mandate urgent surgical treatment mainly due to the need to debride contaminating foreign material such as wadding. Serial debridement may also be necessary to resect necrotic tissues, which often demarcates over time.

Surgical Treatment of Gunshots to the Spine

Stauffer et al.⁴⁰ retrospectively reviewed the role of neurologic decompression in patients with SCI from gunshots. They were unable to identify a benefit in terms of neurologic recovery in ASIA A (complete) SCI patients. Patients with incomplete SCI actually demonstrated a trend toward better neurologic outcome with nonsurgical decompression, though > 70% improved neurologically in both groups.⁴⁰ A high rate of complication, such as infection and fistula, has been reported with surgical decompression alone.^{4,40} Waters has prospectively studied neurologic recovery after surgical treatment. He found that surgical decompression of bullets from the spinal canal is associated with improved neurologic recovery below the T12 level. Improvement of neurologic recovery after bullet removal has not been shown in other regions of the spine. Rare instances of late neurologic decline because of retained bullet fragments have been documented.²⁵ Bono and Heary agreed that retained bullet fragments should be removed from the canal at the cauda equina level when neurologic injury is present.⁴ They also recommend removal of fragments from the canal at the cervical level, though there is limited evidence to support this. They justify the increased risk of infection and cerebrospinal

fluid (CSF) leak with the potential benefit of sparing even one cervical level, since the functional gain achieved can be significant.⁴

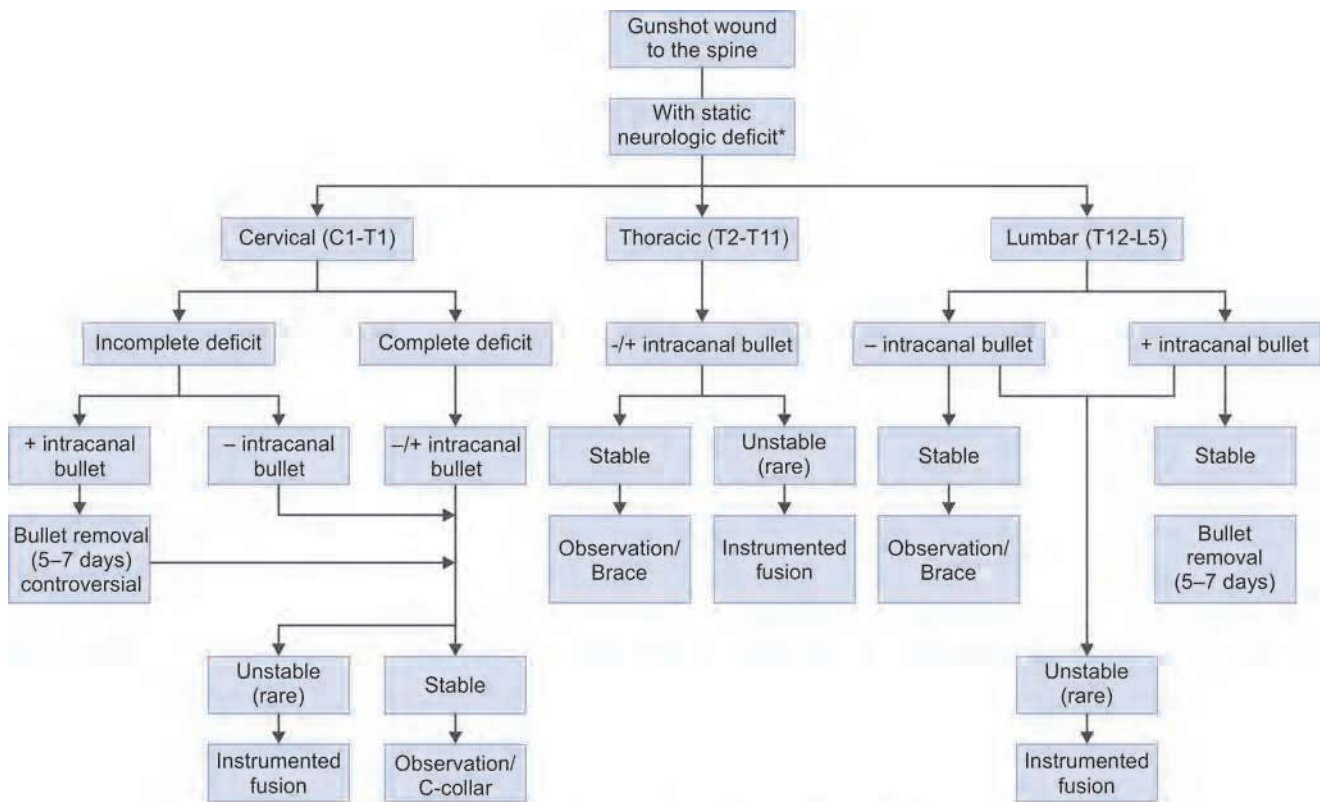

Klimo et al. and Blair et al. reviewed penetrating SCI in military populations.^{7,12} Klimo et al. found that there were serious methodological shortcomings in both the civilian and military literature groups. They, therefore, stated that decompression should be considered for any patient with an incomplete neurological injury and persistent spinal canal compromise, ideally within 24–48 hours of injury. Furthermore, they surmised that the patient should be stabilized if the spinal injury is unstable.¹²

The authors recognized the highly controversial nature of this topic and hoped that their literature review and proposed treatment recommendations would serve as a valued resource, but ultimately felt that the treating surgeon must make the final decision based on his or her opinion of the literature, his or her individual abilities and available resources.¹²

Blair et al. have performed the most up-to-date review of penetrating SCI sustained in a military population.⁷ One of the main weaknesses of the study, like so many of its kind, is that it was retrospective in nature. However, its strength is the completeness of analysis. They noted that penetrating SCI in service members is much more likely to occur from explosives.⁷ This led to blunt and penetrating mechanisms 32% of the time.⁷ Gunshots typically led to isolated penetrating spinal injuries. Blair et al. found that, overall, patients had similar results for neurologic recovery whether treated operatively or nonoperatively. This is obviously a heterogeneous group, because the gunshot and explosive penetrating injuries were not separated. Ultimately, they concluded that decompression should not be performed for complete SCI and for incomplete injuries; it should only be *considered* if clear compressive pathology exists.⁷

As far as timing is concerned regarding surgical decompression of gunshot wounds to the spine, it does not appear to make a difference whether it is performed early (<72 hours) or late, when neurologic recovery is considered, except in the case of progressive deterioration.⁴¹ Other complications such as arachnoiditis or infection may be more likely when surgery is delayed past 2 weeks, whereas CSF leak and durocutaneous fistula may be more common if surgery is done before 5 days.^{40,41} The studies that support these findings have relatively small numbers and suffer

Flowchart 59.1: The algorithm for treatment of gunshots to the spine (devised by Bono and Heary⁴) is outlined. The factors that affect decision-making include location of the spinal injury, location of the bullet, extent and chronicity of neurology, and spinal stability.

*Any progressive neurologic deficit with a radiologically identifiable cause (bullet fragments, bone fragments, compressive epidural hematoma) may warrant urgent decompression regardless of the level of the injury

from methodological flaws that make these conclusions tenuous.

In the presence of a CSF leak that is refractory to conservative management, a lumbar drain can be utilized. If the patient is at risk for developing, or has developed a durocutaneous fistula, surgery is recommended, due to the high risk of meningeal infection and failure to heal.^{22,35} Bono and Heary have devised a treatment algorithm for treating gunshots to the spine, depicted in Flowchart 59.1.

Surgical Treatment of Nonmissile Penetrating Spinal Injuries (Stabbing, etc.)

Nonmissile penetrating injuries to the spinal cord are more rare than gunshots. The information available to guide surgical treatment is loosely based on literature from gunshot data as well as relatively small case series and reports on specific injuries. In contrast to gunshot injuries, there is a greater consensus on surgical treatment of impale-

ment injuries. While it is not typically necessary to remove retained bullet fragments, it is generally recommended that retained foreign material (i.e. knife tip, wire, nail, or other fragments) be removed from the spinal canal to enhance neurologic recovery and decrease infection risk.^{14,16,42-44}

Saeidiborojeni et al. published a 12-year case series on SCIs that resulted from stabbings.¹⁴ About 43% of stab injuries resulted in complete SCI, while 57% were incomplete. There was very little chance of neurologic recovery for ASIA A lesions.¹⁴ Approximately, 70% of incomplete injuries improved.¹⁴ Unfortunately, the authors did not expound upon the role of surgical treatment. The majority of papers that dealt with surgical treatment of nonprojectile (impalement) injuries to the spinal cord were small case series or case reports. They highlighted unique scenarios that may help surgeons guide treatment when similar situations arise.

Wang et al. reported on a case of a wire-penetrating injury to the C6 spinal level.⁴⁴ The patient had a piece of bull whip snap off and impale him in his anterior neck.

The fragment pierced the dura and spinal cord and caused mild paraplegia. It was successfully removed and the CSF leak was easily plugged with bone wax. The patient had near complete neurologic recovery. Manzone et al. also lend support to the premise that removal of retained foreign objects from stabbing injuries can promote neurologic recovery.⁴⁵ They reported on a patient who had been stabbed and had the tip of the knife broken off into the spinal canal. The patient had a stable ASIA grade C neurologic injury for 7 days. After the tip was surgically removed, the patient experienced rapid and near complete neurologic recovery.⁴⁵

A penetrating injury to the cauda equina with wooden fragments has also been reported.⁴⁶ In this case, the patient had delayed neurologic deterioration. The wooden fragments in the spinal canal at the L2 and L3 levels were found on MRI after the patient developed a cauda equina syndrome. The pieces were successfully removed surgically and dural repair was performed.⁴⁶ This case also highlighted the potential for neurologic recovery after foreign body removal. In addition, it highlighted the need for dural repair, which may require patching, fibrin glue and possible lumbar drainage with prolonged recumbency.⁴⁶

KEY POINTS

- Penetrating spinal cord injuries (SCIs) are more likely to be stable compared to SCIs caused by blunt trauma.
- Ballistics and energy delivered via firearm projectiles needs to be a part of assessment in penetrating SCI. Kinetic energy (KE) = $1/2 mv^2$. Bullet velocity exponentially increases KE.
- Tissue damage imparted by gunshot missiles can come from three mechanisms: (1) direct (missile contact) tissue destruction, (2) pressure or shock-wave (concussive effect) or (3) temporary cavitation.
- Antibiotic treatment duration is controversial, but ranges from 48 hours for injuries that do not involve the gastrointestinal tract to upward of 14 days for injuries associated with colonic perforation. No study has proven the efficacy of debridement to the spine to prevent spinal infection.
- Surgical treatment goals for gunshots to the spine may include but are limited to re-establishing spinal stability, neurologic decompression, wound debridement and removal of retained objects to prevent migration or toxicity.

- While it is not typically necessary to remove retained bullet fragments, it is generally recommended that retained foreign material (i.e. knife tip, wire, nail or other fragments) be removed from the spinal canal to enhance neurologic recovery and decrease infection risk.

KEY REFERENCES

Blair JA, Possley DR, Petfield JL, et al. Military penetrating spine injuries compared with blunt. *Spine J*. 2012;12:762-8.

A series of military spinal injuries were studied over 8 years. Concomitant injuries to the abdomen, chest, and head were common in blunt and penetrating spinal cord injury (SCI) patients. Blunt and penetrating injuries to the spinal column and spinal cord occur frequently in the current conflicts in Iraq and Afghanistan. Penetrating injuries result in significantly higher rates of SCI and trend toward increased rates of operative interventions and decreased neurologic improvement at follow-up.

Klimo P, Jr., Ragel BT, Rosner M, et al. Can surgery improve neurological function in penetrating spinal injury? A review of the military and civilian literature and treatment recommendations for military neurosurgeons. *Neurosurg Focus*. 2010;28:E4.

Based on the authors' military and civilian PubMed literature search, most of the evidence suggests that decompressive laminectomy does not improve neurological function in patients with penetrating SCI. However, there are serious methodological shortcomings in both literature groups. Surgical decompression should be considered in military penetrating SCI scenarios for any patient with an incomplete neurological injury and continued spinal canal compromise, ideally within 24–48 hours of injury; the patient should be stabilized concurrently if it is believed that the spinal injury is unstable. The authors recognize the highly controversial nature of this topic.

Waters RL, Sie I, Adkins RH, et al. Motor recovery following spinal cord injury caused by stab wounds: a multicenter study. *Paraplegia*. 1995;33:98-101.

A series of patients with SCI due to stab wounds was studied. Fifty percent of those with motor incomplete lesions had asymmetrical motor patterns indicative of a Brown-Sequard syndrome. Although the percentage of

patients sustaining an incomplete SCI injury following a stab injury to the spine is higher than the percentage of incomplete lesions associated with other etiologies, the amount of motor recovery when controlling for level and completeness of injury is no greater than previously reported for other etiologies.

Quigley KJ, Place HM. The role of debridement and antibiotics in gunshot wounds to the spine. *J Trauma*. 2006; 60:814-9; discussion 9-20.

Surgical treatment of the spine in patients with transgastrointestinal gunshot wounds showed a significantly higher rate of spinal infection than did nonsurgical treatment of the spine. No significant difference in spine infection rate was seen with adequate versus inadequate antibiotic coverage in the transgastrointestinal subset or in the development of wound infections with spine surgery or varying antibiotic coverage. There is a significantly higher rate of spine and wound infections with transgastrointestinal gunshot wounds to the spine. These injuries, particularly those that involve the colon, put patients at risk for the development of spine infections after spinal surgery. Randomized controlled trials are necessary to establish a specific protocol for intravenous antibiotic therapy in the setting of transgastrointestinal gunshot wounds to the spine.

Novel Approaches to Neural Repair and Regeneration after Spinal Cord Injury

INTRODUCTION

Spinal cord injury (SCI) is a complex and potentially devastating event that can lead to permanent disability. The process involves disruption of ascending and descending axonal pathways and an ensuing inflammatory response that results in progressive neuronal loss, axonal destruction and demyelination at the site of injury.

In developing countries, the incidence of SCI is approximately 25.5 cases per million per year.¹ Nearly 10,000 new cases of acute paralysis are documented each year, and social costs are estimated at 10 billion dollars per year in the United States alone.² The vast majority of SCI patients are male (82.8%),¹ who are most frequently between 16 and 30 years of age.³ The two leading causes of SCI are motor vehicle crashes and falls, with complete SCI more common than incomplete injuries (56.6% vs. 43.0%, respectively), and paraplegia more common than quadriplegia (58.7% vs. 40.6%, respectively).¹

PRIMARY INJURY

The pathophysiology of SCIs is multifactorial and multiphasic, including primary and secondary injury mechanisms (Fig. 60.1).⁴ The primary mechanism, as described by Walker et al., involves direct mechanical trauma to the spinal cord.⁵ Clinical outcomes vary depending on numerous factors including the impact of injury, duration

of compression, displacement of the cord, acceleration of impacting forces and the amount of kinetic energy absorbed at the time of injury.^{6,7}

After the primary offense, the propagation of damage is thought to occur through activation of biochemical events leading to cellular dysfunction and death (Fig. 60.2).⁸⁻¹⁰ Of note, the spinal cord undergoes progressive inhibition of recovery that results in additional neuronal damage.^{11,12} The secondary injury is associated with the inflammatory response,¹³ and leads to pathologic changes including hemorrhage, edema, necrosis, axonal fragmentation, demyelination and eventually cyst and scar formation (Fig. 60.3).¹⁴ These processes begin immediately following the injury and continue for weeks.

SECONDARY INJURY

Vascular Damage

The secondary injury cascade generally begins with vascular disruption, including microcirculatory insufficiency.¹² However, the definitive cause of vascular insufficiency after posttraumatic SCI remains unknown.¹⁵ Senter et al. suggested that the mechanism involves the autoregulation of spinal cord blood flow, which is damaged in acute SCI.¹⁶ These patients usually have systemic hypotension and bradycardia from neurogenic shock and decreased sympathetic tone. The loss of autoregulation after SCI results in vascular hypoperfusion due to capillary loss,

Fig. 60.1: Primary and secondary injury mechanisms.

Source: Salewski R, Emrani H, Fehlings MG. Neural stem/progenitor cells for spinal cord regeneration.

vasospasm, thrombosis, and systemic hypotension, which can lead to cellular ischemia and chromatolysis in the anterior horn cells.¹⁷

Some authors have suggested that the severity of cord injury correlates with the degree of post-SCI ischemia, and recovery of neurologic function is dependent on the improvement of blood flow.¹⁸⁻²⁰ For this reason, it has been recommended that mean arterial pressure be maintained at or above 90 mm Hg after SCI.²¹

Oxidative Stress and Lipid Peroxidation

After a temporary period of ischemia, the spinal cord undergoes unregulated reperfusion, resulting in an increase in oxygen-derived free radicals, which may exacerbate the secondary damage.^{22,23} Free radicals are produced in normal cellular processes as a part of the mitochondrial electron transport chain and the microsomal cytochrome P-450 system (Fig. 60.4).²⁴ These free radicals increase in response to brisk reperfusion following oxygen deficit, resulting in the oxidation of cellular membrane lipid fatty acids. This membrane lipid peroxidation produces more free radicals, which in turn leads to more lipid peroxidation, in a chain reaction fashion.²⁵ Free radicals contribute to other related

processes, such as modulation of membrane receptor function, denaturation of DNA and mitochondrial proteins, and inhibition of sodium-potassium ATPase, which lead to metabolic collapse and cell death.^{26,27}

Excitotoxicity

After SCI, intracellular glutamate release occurs secondary to excess free radicals, which then leads to impairment of neuronal membranes, depolarization, and cellular death. Glutamate is the most excitatory neurotransmitter in the central nervous system (CNS) and peripheral nervous system (PNS), and is important for learning and memory and helps regulate brain development.²⁸ However, glutamate must be present in the proper concentrations, and imbalance may contribute to neuronal damage after SCI.

Glutamate receptors are divided into two groups, ionotropic and metabotropic.^{29,30} The ionotropic receptors, which include N-methyl d-aspartate (NMDA), α -amino-3-hydroxy-5-methylisoxazolepropionate (AMPA) and kainate, mediate the passage of calcium and sodium ions. Metabotropic glutamate receptors activate ion channels via G proteins through secondary intracellular messengers.

Fig. 60.2: Glial response and intracellular signaling mechanisms.

Source: Yiu G, He Z. Glial inhibition of CNS axon regeneration. *Nat Rev Neurosci.* 2006;7(8):617-27.

Excessive glutamate activates NMDA receptors, which mediates entry of extracellular calcium into the cell, and trigger the release of calcium from the cytoplasmic compartment.³¹ This increased calcium concentration activates destructive enzymes such as phospholipases and lipoxygenases, which cause cellular damage and death.³²

Immune Response

Inflammation is a part of the complex biological response after injury, and includes cellular (neutrophils, macrophages and T cells) and noncellular components (cytokines, prostaglandins and complements). The CNS is more

Fig. 60.3: Glial scar and cyst formation.

Source: Macaya D, Spector M. Injectable hydrogel materials for spinal cord regeneration: a review. *Biomed Mater.* 2012;7(1):012001.

susceptible than other tissues to the inflammatory and immunologic response.³³

After SCI, the site is initially infiltrated by neutrophils, which secrete lytic enzymes and cytokines that may further damage local tissue and recruit other inflammatory cells.^{34,35} Once active, neutrophils will secrete additional cytokines that stimulate the production of phospholipases and cyclooxygenase.³⁶

Prostaglandins (PGE₂, PGD₂, PGF_{2a}, and PGI₂ in particular) and thromboxanes are produced following oxidation of arachidonic acid by cyclo-oxygenase. Prostaglandins enhance the inflammatory response by altering capillary permeability, as well as activating other inflammatory cells. Thromboxanes also promote platelet aggregation and adherence.³⁷ Macrophages and local microglia produce interleukin-1 β , interleukin-6, and tumor necrosis factor α , which exaggerate the inflammatory response and tissue damage.³⁸

ASTROGLIAL SCAR

In the weeks following SCI, chronic changes occur including the development of a central necrotic region, post-traumatic

Fig. 60.4: Lipid peroxidation by free radicals.

Source: Kwon BK, et al., Pathophysiology and pharmacologic treatment of acute spinal cord injury. *Spine J.* 2004;4(4):451-64.

cysts, and, finally, an astroglial scar. The glial scar is composed of many reactive cells including astrocytes, microglia, endothelial cells, and fibroblasts.³⁹ Astrocytes play a critical role in glial scar formation (gliosis) and inhibition of axonal regeneration.⁴⁰

Gliosis is both beneficial and detrimental. On the one hand, the scar provides a biochemical protection and structural stabilization to cord integrity, thus preventing further damage. Also, the absence of gliosis is associated with impairment of the repair process of the blood-brain barrier.⁴¹ However, secretion of growth inhibitory factors by the surrounding astrocytes prevents axonal regeneration.^{42,43}

INTERVENTIONS FOR ACUTE SPINAL CORD INJURY

After traumatic SCI, a general assessment must include the confirmation and protection of the airway, breathing, and circulation. Early stabilization should be performed if the patient has an unstable fracture in order to prevent further damage.⁴⁴

Pharmacologic or biological agents used in the treatment of acute SCI act either by neuroprotection or regeneration. Neuroprotective agents prevent further inflammation and damage while regenerative strategies attempt to repair the injury site.⁴⁵

Neuroprotective Agents

Methylprednisolone

Methylprednisolone has been used after acute SCI for more than 20 years.⁴⁶ Although the precise mechanism is not completely clear, methylprednisolone may affect modulation of neuronal excitability, improve blood flow, and stabilize the injured spinal cord through inhibition of lipid peroxidation.⁴⁹ Although methylprednisolone

treatment is currently controversial, it remains an option until supplanted by future evidence-based therapies.⁴⁶⁻⁴⁸

The use and effectiveness of methylprednisolone has been assessed in clinical studies such as the National Acute Spinal Cord Injury Studies (NASCIS), a three-staged clinical trial. National Acute Spinal Cord Injury Study I was a multicenter, double-blinded, randomized trial evaluating the efficacy of low-dose (100 mg/day) and high-dose (1,000 mg/day) methylprednisolone for 10 days after acute SCI.⁵⁰ There were no differences in neurological recovery between the two groups at 6 weeks or 6 months. However, the rates of wound infection and early fatalities were higher in the high-dose group. Animal studies have suggested that the dose of methylprednisolone in NASCIS I was not effective for neuroprotection, and the dosage should be about 30 mg/kg.⁴⁹⁻⁵¹

In the NASCIS II trial, a higher dose of methylprednisolone was used, as well as the opiate receptor antagonist naloxone. In this study, 487 patients with acute SCI were randomized into three groups. The first group was treated with a bolus of 30 mg/kg of methylprednisolone, followed by an infusion of 5.4 mg/kg/h for 23 hours. The second group was treated with a bolus of naloxone (5.4 mg/kg), followed by 4.5 mg/kg/h infusion for 23 hours and the third was the placebo group. The authors concluded that treatment with methylprednisolone within 8 hours of injury improves neurological recovery after either complete or incomplete SCI. The authors also found that there was no difference in neurological recovery between the naloxone and placebo groups.⁵²⁻⁵⁴

In NASCIS III, the optimal duration of methylprednisolone treatment, as well as the efficacy of tirilazad mesylate, a lipid peroxidation inhibitor, was evaluated.¹¹ In this study, 499 patients were treated with a methylprednisolone bolus (30 mg/kg) within 8 hours and then randomized into three groups. The first group received an infusion of 5.4 mg/kg methylprednisolone for 24 hours and, in the second group, the infusion continued for 48 hours. The third group was treated with an infusion of 2.5 mg/kg of tirilazad mesylate every 6 hours for 48 hours.^{13,55} The authors concluded that if methylprednisolone treatment were initiated within 3 hours after SCI, the infusion should be maintained for 24 hours, and for 48 hours if initiated within 3–8 hours.

Gangliosides

Gangliosides are found in neuronal cell membranes, and the prototypical ganglioside GM1 (monosialotetrahexosylganglioside) is important for neuronal plasticity and

repair.^{56,57} Exogenous GM1 treatment has been associated with neuronal protection by preventing the decay of enzymes such as lactate dehydrogenase and Na⁺-K⁺-ATPase, preventing inflammation and demyelination, and inhibiting excitotoxicity.⁵⁸⁻⁶¹ While one study found improvements after treatment with GM1 after SCI at 8 weeks, this improvement was not seen at 6 months.⁶² Geisler et al. also found no difference in American Spinal Injury Association (ASIA) score in patients treated with GM1 or placebo.⁶³

Opioid Antagonists

After SCI, there is a reduction in blood pressure and perfusion of the spinal cord.⁶⁴ Opioid antagonists such as naloxone prevent pathological changes and promote motor recovery by improving spinal cord blood flow.^{65,66} Naloxone also blocks the κ -opioid receptor, which reduces inflammation.^{67,68} However, in the NASCIS II trial, patients treated with methylprednisolone along with naloxone did not show significantly greater recovery.⁵³

Thyrotropin-releasing hormone (TRH) and its analogs act as partial opioid antagonists, and improve neurologic recovery after SCI through mechanisms that remain unclear.^{69,70} White et al. suggested that TRH may facilitate transmission in somatosensory pathways, enhance sympathetic outflow from the spinal cord, and play a role in somatic motor neuron excitability.⁷¹

Glutamate Antagonists

Excitotoxicity is characterized by excessive glutamate release through NMDA and non-NMDA (AMPA/kainate) receptor activation after SCI. N-methyl D-aspartate receptor antagonists such as gacyclidine (GK-11),⁷³ dizocilpine (MK-801), and Cerestat (CNS-1102)⁷² have demonstrated significant neuroprotective effects in several studies.^{73,74}

The effects of gacyclidine include a decrease in the diameter of the ischemic lesion, and an improvement in functional recovery through prevention of excitotoxic cell death.^{75,77} Gaviria et al. suggested that the effects of gacyclidine are time and dose dependent,⁷⁶ and Hirbec et al. confirmed that optimal protection is obtained when gacyclidine is administered within 30 minutes of injury.⁷⁷

Ion Channel Blockers:

Calcium Channel Blockers

Nimodipine, a calcium channel blocker, has been examined to prevent excess calcium entry into the neuronal cell. However,

the predominant effect of nimodipine on the cord is by the way of increased blood flow through the prevention of calcium-mediated vasoconstriction.^{78,79}

Because of nimodipine causes hypotension, which can lead to hypoperfusion of the spinal cord, some authors have suggested that vasopressor therapy such as norepinephrine may be supplemented with nimodipine treatment to improve perfusion and neurologic recovery.^{80,81} Animal studies have not demonstrated significant neurologic recovery with nimodipine treatment after SCI.⁸²⁻⁸⁴

Sodium Channel Blockers

Riluzole is an Food and Drug Administration (FDA) approved sodium channel blocker used for the treatment of amyotrophic lateral sclerosis.^{85,86} Excessive activation of sodium channels is associated with cellular toxicity and neuronal degeneration. Blocking of these channels may reduce the secondary inflammatory response, and improve neurologic recovery after SCI.⁸⁷ Multiple independent studies have suggested that sodium channel blockers exhibit significant neuroprotective effects after SCI, especially in the early stages.⁸⁵⁻⁸⁹

Nonsteroidal Anti-inflammatory Drugs

After SCI, prostaglandins play important roles in the inflammatory response. Nonsteroidal anti-inflammatory drugs are generally used to relieve pain and inflammation by preventing the synthesis of prostaglandins through the inhibition of cyclo-oxygenase enzymes. Ibuprofen and indomethacin have been shown to improve axonal growth and functional recovery via suppression of the intracellular RhoA signal in an animal model.^{90,91}

Erythropoietin

Erythropoietin (EPO) is another potential therapeutic agent that stimulates the proliferation and differentiation of erythroid precursor cells. The beneficial effects of EPO are thought to be due to impending apoptosis, its inherent anti-inflammatory effects, and the restoration of vascular integrity and neuronal regeneration.⁹²⁻⁹⁵ Studies have suggested that EPO demonstrates neuroprotective and neuroregenerative effects after SCI in a rat model.^{96,97}

Minocycline

Minocycline, a second-generation tetracycline, has been shown to inhibit excitotoxicity⁹⁸ and exert neuroprotective

effects.⁹⁹ In an animal model, minocycline appeared to improve functional recovery by eliminating the destructive processes of the secondary injury.¹⁰⁰

Immunosuppressants

Cyclosporine A (immunophilin) and FK-506 (tacrolimus) are the most commonly used immunomodulatory agents that have demonstrated neuroprotective and neuroregenerative effects after SCI.¹⁰¹⁻¹⁰³ These immunosuppressants exhibit their effects through various mechanisms, principally by lowering the activity of T cells, but also through antioxidant effects, replenishing ATP stores, decreasing myeloperoxidase levels, inhibiting mitochondrial swelling, and decreasing oxidative stress.¹⁰¹⁻¹⁰⁴

Chondroitinase

Chondroitin sulfate proteoglycans (CSPGs) are potent inhibitors of axonal regeneration in the adult CNS.^{105,106} Several studies have suggested that inhibition of CSPGs using chondroitinase ABC improves functional recovery after SCI. The proposed mechanisms of action include promoting regeneration and neuroprotection of damaged axons, increasing the plasticity of uninjured pathways, and limiting scar tissue.¹⁰⁷⁻¹⁰⁹

Ethyl Pyruvate

Pyruvate, an organic acid, supplies energy to living cells through the Krebs cycle and prevents neuronal damage as a free radical scavenger for hydrogen peroxide.¹¹⁰⁻¹¹² Treatment using ethyl pyruvate has demonstrated a neuroprotective effect after SCI through inhibition of astrogliosis and neuroinflammation, as well as improved neuroregeneration via antioxidative properties in mouse and rabbit models.¹¹³⁻¹¹⁵

Atorvastatin

Atorvastatin (trade name Lipitor) is a member of the statin family used for lowering blood cholesterol by inhibiting HMG-CoA reductase. This compound also demonstrates anti-inflammatory properties.¹¹⁶ In animal models of SCI, treatment with atorvastatin has been shown to be neuroprotective by decreasing the inflammatory response of the secondary injury, and by reducing neuron and oligodendrocyte apoptosis.¹¹⁷⁻¹¹⁹

Alprostadi

Alprostadi, an analog of prostaglandin E1 (PGE1), improves motor function after SCI by increasing spinal cord blood flow,¹²⁰ reducing inflammation,¹²¹ and upregulating the expression of vascular endothelial growth factor.^{122,123} This vasoactive agent may prove to be effective in the treatment of SCI.

Neuroregenerative Strategies

Cell Transplantation

Cell-based therapies to repair damaged neuronal cells are a promising new concept for the treatment of SCI. The cell types used include bone marrow stromal cells (BMSCs), human embryonic stem cells (HESCs), olfactory ensheathing cells (OECs), and induced pluripotent stem cells (iPSCs).¹²⁴ However, there is currently no consensus on what type of stem cell or progenitor cell would be the ideal source for cellular grafts.¹²⁵ Growth factor (GF) secretion is observed after transplantation of these cells.¹²⁶ These GFs also exhibit antiapoptotic effects and improve axonal regrowth, remyelination, and neuronal plasticity.^{127,128}

Bone Marrow Stromal Cells

Bone marrow stromal cell is a unique cell that can differentiate into glial and neuron-like cells, as well as cells expressing markers of immature neurons.^{129,130} Several animal studies have suggested that BMSC transplantation after SCI can promote repair of the injured spinal cord and recovery of neurological and locomotor functions.¹³¹⁻¹³⁴ Ide et al. examined the effects of BMSCs in a rat model of subacute SCI lesion. Two weeks after SCI, cultured BMSCs derived from GFP-transgenic rats were transplanted directly into the lesion. Fourteen days after transplantation, cavity formation was reduced, and locomotor recovery was improved compared to the control group.¹³⁵

Cotransplantation of BMSCs with various cells and factors has also been studied. The addition of Schwann cells (SCs) reduces the formation of glial scar, remyelinate the injured axons, and promotes functional recovery.¹³⁶⁻¹³⁹ Cotransplantation of BMSCs with olfactory ensheathing cells,^{140,141} stimulating factors, such as granulocyte macrophage-colony stimulating factor,¹⁴² brain-derived neurotrophic factor (BDNF),¹⁴³ and other GFs¹⁴⁴ have all been shown to improve functional recovery.

Paul et al. compared delivery methods for cell transplantation using either lumbar puncture (LP) or intravenous delivery in a rat model. They concluded that both methods of cell transplantation were effective, but in LP delivery, cell engraftment and tissue sparing were significantly better, and the host immune response was reduced.¹⁴⁵

Olfactory Ensheathing Cells

Olfactory ensheathing cells are the glial cells of the olfactory system, also known as olfactory SCs. Olfactory ensheathing cells are different from the glial cells of other systems because of their developmental origin and presence in both the peripheral and CNSs. Olfactory ensheathing cells create olfactory axons from the nasal epithelium to the olfactory bulb.^{146,147} Olfactory ensheathing cells also secrete GFs that support new olfactory axons and promote axonal regeneration after SCI.¹⁴⁸ Several studies have suggested that OEC transplantation promotes neural regeneration and improves functional recovery^{141,149-151} via multiple mechanisms including promotion of tissue sparing,¹⁵² stimulation of axonal regeneration,¹⁵³ and reduction in secondary damage by modulating inflammation.¹⁵⁴

Lu et al. demonstrated that transplantation of OECs can promote axonal regeneration after SCI. In a rat model, they transected the thoracic spinal cord at the T10 level. After 4 weeks, OECs were transplanted into the spinal cord. Ten weeks later, locomotor activity of these rats was significantly improved compared with the control group.¹⁵²

Human Embryonic Stem Cells

Human embryonic stem cells are pluripotent stem cells derived from totipotent cells of the early-stage embryo.^{155,156} Many researchers have found that after SCI, treatment with HESC transplantation may have potential therapeutic effects, including improvement of functional recovery and axonal regeneration.¹⁵⁷⁻¹⁶³ These cells may prove to be a useful therapeutic strategy to repair the injured spinal cord.

Kerr et al. transplanted oligodendrocyte progenitor cells (OPCs) derived from HESCs into a contused SCI rat model at 3 and 24 hours following injury. The authors found that the cells survived for a minimum of 8 days, and migrated away from the injection site after 1 week. They also found increased neurological responses in the OPC group compared to controls.¹⁶⁴

Induced Pluripotent Stem Cells

Induced pluripotent stem cells are a type of pluripotent stem cell artificially derived from nonpluripotent cells by transducing different genes.¹⁶⁵⁻¹⁶⁷ Because IPSCs can be developed from a patient's own somatic cells, it was believed that treatment with IPSCs would elude any immunogenic response, while circumventing potential ethical dilemmas.^{168,169} However, IPSCs are associated with a potential risk of tumor formation due to inappropriate reprogramming of somatic cells and through transduction with retroviruses and lentiviruses, which activate exogenous transcription factors. The safety and effectiveness of IPSC treatment should be assessed prior to clinical use, including the differentiation potentials and tumorigenic activities.¹⁷⁰

In recent years, IPSCs have been produced without using a viral vector. Using IPSCs without inserting exogenous genes appears safe and preferable.^{171,172} Animal studies suggest that IPSC treatment using newer delivery models promotes functional recovery without tumor formation.^{169,170,173,174}

Growth Factors

Astrocytes are involved in the regulation of SCI, and are vital for neuroprotection and metabolic support.^{175,176} After SCI, astrocyte precursors surround the lesion and enhance the upregulation of epidermal growth factor receptor (EGFR), which is necessary for neuroprotection and normal glial scar formation. Transforming growth factor alpha (TGF- α) exhibits mitogenic effects that enhance astrocyte invasion and axon regeneration through activation of the EGFR. Infusion of TGF- α into the injured spinal cord enhances astrocyte infiltration and axonal growth, and may be a potential treatment strategy.^{177,178}

Brain-derived neurotrophic factor, a member of the neurotrophin family of GFs, stimulates growth and mediates the survival of existing neurons and the differentiation of new neurons.¹⁷⁹ Several studies have suggested that administration of BDNF after SCI is associated with better neurological regeneration and improved functional outcome,¹⁸⁰⁻¹⁸⁴ possibly due to this factor's ability to promote axonal regeneration, plasticity and remyelination.¹⁸⁵

Biomaterials

Biomaterials have been developed in attempts to bridge the area of injury with a bioengineered scaffold with chemical and physical properties to create a stimulatory and permissive milieu.¹⁸⁶⁻¹⁸⁸ Approaches that combine

biomaterials with drugs to carry and deliver cells to the injured cord could improve tissue repair and functional recovery.¹⁸⁹⁻¹⁹² Several studies have suggested a synergistic effect favoring neural regeneration¹⁹³ when biomaterials were combined with BMSCs,¹⁹⁴⁻¹⁹⁶ SCs¹⁹⁷ and OECs.¹⁹⁸

Macrophage Transplantation

Neuronal regeneration of the injured spinal cord is restricted because of limited immune response and insufficient macrophage recruitment.¹⁹⁹ Several studies have demonstrated that treatment with macrophage transplantation after SCI improves neuronal repair by releasing cytokines and promoting a permissive extracellular environment.²⁰⁰⁻²⁰² However, in a large-animal SCI study, autologous macrophage implantation did not improve neuronal regeneration.²⁰³

Rho Antagonists

The role of Rho, a small GTPase, which plays an important role in the intracellular signaling pathways in the axonal tip (growth cone), has been extensively studied and drug interventions targeting this pathway are in the initial phases of clinical trials.²⁰⁴ Leakage of myelin proteins and the process of gliosis after SCI lead to activation of Rho, causing neuronal apoptosis that leads to a block in neuronal attempts to regenerate.²⁰⁵ Rho antagonists, thus, have a potential neuroregenerative role in promoting axonal regeneration and sprouting. Novel anti-Rho molecules like BA-210 (Cethrin) have shown encouraging results in phase 1 and phase 2a trials and may soon find wider clinical application.²⁰⁴

Anti-Nogo Antibodies

Antibodies against the myelin-associated protein "Nogo-A" present in oligodendrocytes and their membranes have shown to result in upregulation of growth-specific proteins and enhanced regenerative and compensatory sprouting of fibers.²⁰⁶ Phase 1 clinical trials applying anti-Nogo A antibodies have been promising and currently phase 2 trials are on the way.²⁰⁶

CONCLUSION

Spinal cord injury is a potentially devastating traumatic event resulting in death of neuronal cells, degeneration of axons, gliosis, and functional deficit. There is currently no curative treatment for SCI.

Because the pathophysiology of SCI is multiphasic and multifactorial, an effective treatment will likely require a combination of therapeutic approaches that promote neuroprotection to prevent further damage, minimize the inflammatory response and stimulate regeneration. Neuroregenerative treatment strategies facilitate repair of the damaged neuronal tissues and include cell transplantation, allograft treatment, GFs, macrophage transplantation, and biomaterial engineering. Recent studies have demonstrated that cell transplantation strategies hold promise in improving neural cell regeneration and functional recovery after SCI.

KEY POINTS

- Gliosis contributes to inhibition of axonal regeneration, as well as biochemical protection and structural stabilization.
- Neuronal regeneration after SCI is limited.
- Reducing inflammation and astroglial scar is a key target for treatment.
- Combination treatment strategies could be effective.

INTRODUCTION

The spinal cord injury patient often presents with a complex set of injuries requiring the cooperation of multiple medical services as well as management of multiple physiologic systems in order to generate optimal treatment results. These patients may have suffered polytrauma involving musculoskeletal damage, as well as neurologic or visceral injuries. They may be subject to prolonged periods of intubation, multiple procedures (either tests or surgical), and prolonged periods of bed rest. Their bodies are subject to the initial injury, surgical procedures, prolonged periods of time without oral intake, and risk of infection, which are all ultimately extremely taxing. In order for the body to withstand this process, heal, and fight off infection, elevated energy expenditure is required; and, therefore, optimal nutrition is a key component to patient care. At this juncture, strict nutritional recommendations based on spinal cord injury specific research are not yet clearly delineated.

However, based on current knowledge of the physiologic response to injury, the metabolic and hormonal environment of the critically ill or injured patient, postoperative requirements of the spine surgery patient, and current trends in nutritional management of these individuals, general management guidelines can be extrapolated.

Regarding spinal cord injury patients specifically, the acute phase of injury and treatment can be extremely threatening; however, the condition of the patient after stabilization, may require long-term observation, management, and preparation in order to avoid complications which can develop as a result of the patient's new chronic condition. Nutritional management becomes an important component of the overall care of these patients in order to promote a favorable biochemical environment for healing, prevention of infection and tissue compromise, as well as surgical optimization.

INTRODUCTION TO NUTRITIONAL REQUIREMENTS AND ENERGY EXPENDITURE

Energy is expended by the human body in three forms: resting energy expenditure, the thermic effect of food, and energy expended in physical activity. Resting energy expenditure generally constitutes the largest portion (approximately 60–75%) of the total energy expenditure.¹ The thermic effect of food typically represents roughly ten percent of daily total energy expenditure. Energy expended in physical activity is, therefore, the most variable. Resting energy expenditure is the energy utilized during the

activities necessary to maintain homeostasis including, circulation, respiration, cellular metabolism, maintenance of function of the central nervous system and core body temperature.

Regarding commonly utilized terminology, basal energy expenditure differs from resting energy expenditure and simply refers to “the minimal amount of energy expended that is compatible with life.”¹ Basal metabolic rate measurements are specific regarding the circumstances under which they are taken. These measurements are performed early in the morning, prior to physical activity and ten to twelve hours after the ingestion of food, fluids, or stimulants such as caffeine or nicotine. This calculation often represents 60–70% of daily total energy expenditure. If these specific are not met at the time of measurement, the calculation is then referred to as resting metabolic rate, which, in most cases, is higher.

Many factors have the potential to influence resting energy expenditure including body size, body composition, age, sex, and hormonal factors. In general, larger people have higher metabolic rates than smaller people. If two people are the same weight, the taller of the two will have the higher metabolic rate due to larger surface area. The major single determinant of resting energy expenditure is fat free mass or lean body mass. Based on this trend, athletes with increased muscle mass will tend to have a roughly five percent higher resting energy expenditure than a non-athlete. Age is related to fat free mass. As a result, the aging process may produce a resting energy expenditure which decreases at an average of two to three percent per decade of life after early adulthood. Differences based on sex are generally the result of differences in body composition and lean body mass. Metabolic rate can also be affected by hormonal status, particularly thyroid disorders (hyper versus hypo). Fevers as well as extremes in ambient temperature can affect energy expenditure. Regarding the febrile state, this rate may increase at an average of seven percent per degree Fahrenheit increase above 98.6 (13% for each degree Celsius above 37).

The standard unit of measuring nutritional energy is the calorie. This unit is defined as the amount of heat required to raise the temperature of one mL of water at 15°C by one degree. There are a variety of methods by which human energy expenditure can be measured, some more practical than others in the clinical setting. Indirect calorimetry estimates energy expenditure by measuring oxygen consumption and carbon dioxide production of the body over a given period. “The equipment varies, but

the person usually breathes into a mouthpiece or ventilated hood through which his or her expired gases are collected.”¹ Moles of CO₂ expired are divided by Moles of O₂ inspired to calculate the respiratory quotient. This number is converted to kilocalories of heat produced per square meter of body surface per hour, which is then, in turn, extrapolated to 24 hours. The respiratory quotient (RQ) is specific to the fuel mixture being metabolized. For example, The RQ for carbohydrates is 1, because the number of carbon dioxide molecules produced is equal to the number of oxygen molecules consumed (RQ = 1 for carbohydrate, 0.85 for a mixed diet, 0.82 for protein, and 0.7 for fat). Equations have also been developed to estimate basal and resting metabolic rates. The Harris-Benedict formulas, first developed in 1919, are some of the most widely used in the United States but have been found to overestimate by 7% to 24%. New equations have also been formulated in order to correct for this overestimation. New predictive equations, incorporate individual factors in order to arrive at a more specific calculation. These factors include life-stage grouping, age, weight, height, gender, and level of physical activity. These factors are incorporated in order to calculate the estimated energy requirement. Energy required to perform functions above this baseline, including growth in children, lactation in women, or healing in patients requires an additional calculation to factor for energy required for deposition of tissue.

Original Harris-Benedict equations:

Men	$BMR = 66.4730 + (13.7516 \times \text{weight in kg}) + (5.0033 \times \text{height in cm}) - (6.7550 \times \text{age in years})$
Women	$BMR = 655.0955 + (9.5634 \times \text{weight in kg}) + (1.8496 \times \text{height in cm}) - (4.6756 \times \text{age in years})$

The Harris-Benedict equations revised by Roza and Shizgal in 1984:

Men	$BMR = 88.362 + (13.397 \times \text{weight in kg}) + (4.799 \times \text{height in cm}) - (5.677 \times \text{age in years})$
Women	$BMR = 447.593 + (9.247 \times \text{weight in kg}) + (3.098 \times \text{height in cm}) - (4.330 \times \text{age in years})$

■ PRINCIPLES OF NUTRITIONAL SUPPORT FOR THE ILL OR INJURED PATIENT

Response to stress, whether the source be illness, trauma, or surgery, may lead to shock or other severe outcomes. This response is mediated through metabolic and hormonal pathways, characterized by increased catabolism, negative

nitrogen balance, and muscle wasting. There are two phases to this response as described by Cuthbertson in 1979. The ebb phase occurs immediately following injury and is associated with hypovolemia, shock, and tissue hypoxia with decreased cardiac output, oxygen consumption and body temperature. Insulin decreases, glucagon increases, and hepatic glucose production is augmented. The flow phase, which follows fluid resuscitation and restoration of oxygen transport to tissues is characterized by increased cardiac output, oxygen consumption, body temperature, and total protein catabolism. Glucose production increases as do circulating levels of glucagon, cortisol, catecholamines, insulin, and free fatty acids. Severity of injury, previous state of health, and age all seem to be associated with variability of this response.

Severe physical stress results in marked hyperglycemia, mobilization of acute phase proteins, and increased lipolysis. Branched chain amino acids are mobilized from skeletal protein to be utilized as a source of energy, while increased lipolysis leads to production of free fatty acids which are then metabolized to produce ketones (for energy production in non-glucose-dependent tissues or to resynthesize triglycerides). Potassium, phosphorous, and magnesium are all lost through urinary excretion as a result of increased protein metabolism. Epinephrine, aldosterone, and vasopressin are all increased in response to stress. Gluconeogenesis increases as does sodium and water retention to support circulating blood volume. Tissue damage and inflammation lead to production of cytokines including IL-1,6, and TNF. These metabolically active cytokines also induce gluconeogenesis and amino acid breakdown. IL-1 plays a particular role in regulating the acute phase response to stress characterized by fever, leukocytosis, skeletal muscle breakdown, and decreased serum iron and zinc.²

Regarding the management of the severely traumatized patient, one of the most severe complications can be SIRS (systemic inflammatory response syndrome). [This syndrome can be produced by a variety of stimuli including infection, ischemia, burns, pancreatitis, hemorrhagic shock and immunologically mediated organ injury.³] SIRS is diagnosed according to a strict set of criteria including body temperature above 38°C or less than 36°C, heart rate more than 90 beats/min, respiratory rate greater than 20 breaths/min, PaCO₂ less than 32 mm Hg, WBC count above 12,000/mm³ or less than 4,000/mm³, and bandemia (more than 10% immature neutrophils in the absence of chemotherapy induced neutropenia and leukopenia. Multiple

organ dysfunction can result. One particular hypothesis regarding the generation of this clinical scenario relates to gut health and the importance of enteral nutrition. This gut hypothesis indicates that disruption of the gut barrier function due to trauma corresponds with translocation of enteric bacteria into mesentery lymph nodes, liver and other organs. Enteral nutrition may act to alter antigen exposure, modulate splanchnic immune response, enhance mucosal protection, and enhance oxygen delivery to the mucosa as a result of increased vascular flow. Decreased enteral feeding can lead to villous atrophy, decreased intestinal absorption, and blunted immunity at mucosal surfaces in the gut and other regions of the body—including the lungs, due to migration of cells produced in gut associated lymphoid tissue.⁴

Energy expenditure, and therefore, nutritional requirements can be estimated for the critically ill or injured patient by methods discussed earlier which include Harris Benedict equations (incorporating age, height, weight, and stress factor (of 1.3), Indirect calorimetry, or pulmonary artery catheterization). A general estimate of 25–35 kcal/kg/day is sometimes utilized as well. Indirect calorimetry can be confounded in the critically ill patient by high oxygen requirements secondary to acidosis, a chest tube and the use of supplemental oxygen. Calculated requirements can produce overestimations secondary to paralysis necessary for intubation by as much as 30%. Data can be obtained from a pulmonary artery catheter (often placed in order to tightly monitor and manage cardiopulmonary function in the critical patient) regarding oxygen consumption based on the arteriovenous oxygen difference. The cardiovascular Fick equation can then be applied to this data to calculate cardiac output, which, in turn can be used to extrapolate energy expenditure by incorporating the known caloric value of oxygen.

Fick equation application as explained by Liggett et al. (CHEST, April, 1987):⁵

$$VO_2 = CO(CaO_2 - CvO_2) \times 10$$

where CaO₂ and CvO₂ are the oxygen contents of arterial and mixed venous blood in volumes percent, CO is cardiac output in liters per minute and VO₂ in milliliters per minute. Using 1.36 mL/g as the oxygen-combining capacity for hemoglobin, ignoring the contribution of dissolved oxygen, the following equation is obtained:

$$VO_2 = CO \times 13.6 \text{ Hgb} (SaO_2 - SvO_2)$$

The caloric value of oxygen ranges from 4.69 kcal/L to 5.05 kcal/L as the nonprotein RQ (respiratory quotient) varies within the physiologic range from 0.7 to 1.0, respec-

tively. Liggett chose a fixed nonprotein RQ of 0.85, which has a caloric value of 4.86 kcal/L. Energy expenditure in kilocalories per day (with 1440 min/day) is therefore expressed:

$$\text{REE} = \text{VO}_2 (4.86 \times 10^{-3}) \times 1440$$

Substituting equation 2 into equation 3 and combining all fixed constants, the following equation is obtained:

$$\text{Resting energy expenditure} = \text{CO} \times \text{Hgb} (\text{SaO}_2 - \text{SvO}_2) \times 95.18$$

The REE is expressed in kilocalories per day, CO in liters per minute, Hgb in grams per deciliter, and SaO_2 and SvO_2 in fractions.

Based on calculation of energy expenditure, nutritional support can be administered with an appropriate breakdown of macronutrients, including carbohydrates, proteins, and fats. Protein requirements are significantly higher in the traumatized patient, averaging 2 g/kg/day of body-weight according to ASPEN (American Society for Parenteral and Enteral Nutrition) Board of Directors guidelines (2002). The unstressed adult patient requires an average of 8 g/kg/day. There are no specific guidelines for administration of micronutrients including vitamins and mineral. Electrolytes should be closely monitored and replenished as needed. It should be noted, however, that catabolism may lead to loss of potassium, magnesium, zinc, and phosphorus and an increased need for B vitamins.

NUTRITIONAL SUPPORT STRATEGIES IN TRAUMA PATIENTS

Malnutrition is associated with impaired immune function and subsequent increased risk of infections in trauma patients.⁶ Oral feeding is always the preferred route if possible. If this is not possible due to the patient's specific clinical issues, other routes of enteral feeding should be considered as should parenteral supplementation, if energy requirements are not met by enteral feeding alone. Enteral feeding may require direct access to the gastrointestinal tract through a nasogastric, duodenal, or jejunal feeding tube. Placement of such a tube may play a role in patient care if extended periods of inability for oral feeding are expected. Difficulties of enteral feeding may result from gastric dysmotility due to intestinal insult and neuromuscular paralysis which decrease the likelihood of movement of food through the GI tract. These patients may also require TPN. Early enteral feeding has proved beneficial; yet, it should not be initiated until hemodynamic stability is achieved. Feeding the gut during periods of intestinal

hypoperfusion can increase the risk of intestinal ischemia and necrosis.

Multiple studies have been performed attempting to draw conclusions regarding the roles of specific feeding methods including enteral and parenteral methods. Many, in fact, directly compare TPN to enteral nutrition administration, and range from animal models to clinical studies. Border and associates retrospectively examined the effect of enteral feeding on the ICU treatment course of 66 blunt trauma patients. Enteral protein intake was associated with a reduction in septic severity even though the patients nourished parenterally received twice the amount of protein than the enteral fed group. Kudsk and associates randomized 98 patients into groups receiving either enteral or parenteral nutrition. These patients included those who suffered major blunt abdominal trauma, or penetrating trauma. There were no significant differences in nitrogen balance between the two groups. However, a significantly lower incidence of pneumonia, intra-abdominal abscesses, and catheter sepsis was observed regarding the enteral nutrition group. Incidence of infectious complication was measured as six to seven times greater in the patients receiving TPN. For patients suffering injuries of greater severity, the rate was at times eleven times higher. This same study also demonstrated that enteral feeding produced a greater amount of constitutive proteins and greater decreases of acute phase proteins.⁷ Generally, enteral nutrition seems to have a greater effect on aiding in prevention of infection in the critically ill patient than parenteral routes when used individually. This, however, does not discount the role of parenteral nutrition completely.

In fact, enteral feeding can lead to specific complications and difficulties not observed in patients receiving parenteral nutrition. In their study, Engel et al. recognized that, based on indirect calorimetry measurements, critical patients received on average 71% of their energy expenditure via enteral feeding. On 46% of days, patients received less than 80% of their daily energy expenditure. Factors associated with hypocaloric feeding were recognized in this study and included blunt abdominal trauma, pelvic and lumbar spine trauma, gastrointestinal intolerance, problems with the feeding tube, surgical interventions, and use of fentanyl. Based on this study, it appears that in many clinical scenarios, enteral feeding alone seems insufficient to cover the energy demands of a critically ill or injured patient in a surgical ICU. A relevant reason delineated by this study, which applies directly to the spinal trauma or cord injury patient, is that spinal trauma is positively cor-

related with a higher likelihood of the development of problems with enteral delivery of nutrients. Based on these conclusions, questions may be raised on how to bridge the gap in energy requirement and nutrition administered. If such issues in delivery of adequate nutrition enterally are common, perhaps there is a role for total parenteral nutrition as a supplement to other routes of feeding. The answer to this question has not been clarified and further research on this topic may help to better understand the potential for an interplay between both feeding modalities.

Nutritional supplementation is controversial in the setting of critically ill patients. Certain enteral formulas have been developed specifically for the traumatized or critically ill patient. These formulas typically incorporate a higher protein content as well as a higher portion of branched chain amino acids with the addition of glutamine and arginine. Regarding TPN, glutamine supplementation of these formulas may partially reverse mucosal atrophy, limit the reduction of intestinal immunoglobulin A and improve upper respiratory immunity (in mice). There is promising laboratory data on the effects of glutamate supplementation on nutritional support in mice,⁸ and should be considered in this patient population.

Investigations regarding hormonal supplementation in the trauma patient do exist and seem to be conflicting. Growth hormone administration has been researched and has been shown to improve protein and fat metabolism, with improved nitrogen balance in the trauma patient with low growth hormone levels.⁹ In 1994, two large, randomized, placebo-controlled European multicenter studies detailed the effects of growth hormone treatment in critically ill intensive care patients. Major increases in mortality and morbidity were associated with growth hormone treatment. The mechanism(s) accounting for the increased mortality remain poorly understood. These negative findings have led to a decrease in the clinical use of growth hormone and research activity regarding the area of anabolic treatment for human illness.¹⁰

NUTRITION IN THE ACUTE SETTING AND THE INTERPLAY BETWEEN ENTERAL AND PARENTERAL NUTRITION

Klein et al.¹¹ took a broad perspective regarding the analysis of nutrition with regards to the spine surgical patient. In their three-part study, three different groups of patients were analyzed. In part I, 27 patients (14 men and 13 women

with a mean age of 54 years) undergoing intervention for treatment of vertebral osteomyelitis were evaluated. Fourteen patients with either a total lymphocyte count less than 1500/mm³ or serum albumin less than 3.5 were considered malnourished. Additional data collected included age, pathologic diagnosis, past medical history, American Society of Anesthesiologists (ASA) score, length of surgery, and estimated blood loss. Outcome variables included postoperative complications and length of hospitalization. Regarding part I, postoperative complications were statistically significant as related to findings of preoperative malnourishment. The cohort for part II was comprised of 20 patients (17 men and three women, mean age of 35 years) undergoing surgery for treatment of spinal cord injury. The follow-up period averaged three years although, as in part I, the 'critical' data were from the perioperative period according to authors. Patients were divided into two groups based on postoperative nutritional status, while additional data included age, sex, type and level of injury, past medical history, ASA score, use of high-dose steroid protocol, length of surgery and estimated blood loss. Outcome variables included postoperative complications, need for prolonged intubation (>24 hours), and length of hospitalization. Data on the spinal cord injury patients indicated that 75% of the patients (15 of the 20 included) became malnourished in the postoperative period based on measurements of serum albumin and total lymphocyte count. 17 complications were noted in this part of the study, all found in the malnourished group. [These complications included pneumonia and atelectasis (nine), occipital decubiti (two), urinary tract infection (two), coagulopathy (one), infectious gastroenteritis (one), sepsis (one), and deep venous thrombosis (one).]¹¹ Although researchers found a statistically significant relationship between nutritional status and prolonged intubation, no other perioperative factors were significantly related to postoperative complications. In both groups (patients treated for infections and patients treated for injury), the postoperative complications were seen almost exclusively in the malnourished patients.¹¹ In part III, the researchers intended to address a broader patient population by evaluating data collected for 114 patients who underwent elective lumbar decompression and fusion. Likewise, the majority of complications found in part III of this study were noted to take place in patients deemed to be clinically malnourished. Prospective data collected over a three-year period (with attention to that collected during the perioperative period) was reviewed retrospec-

tively. Regarding these elective cases, 25% of these patients were found to be clinically malnourished at the time of surgery. This value increased to 42% for patients over the age of 60. Regarding data pertaining to part III, it can be argued that the overall rate of clinical malnutrition, even in patients undergoing elective surgery, is significantly higher than anticipated and offers evidence to evaluate these values preoperatively to avoid increased hospital stay, complication rates, lengthy management, and increased cost postoperatively. This study focuses attention on the importance of sound nutrition in the spine surgery patient and raises questions on how to best optimize nutritional status preoperatively and postoperatively.

NUTRITIONAL SUPPORT AND THE SPINE SURGERY PATIENT

Additional information regarding spine specific surgical intervention and nutrition can be extrapolated from nutritional studies incorporating spinal deformity patients. In 1997, Hu et al. published their data collected from a cohort of 35 patients. These adult patients underwent staged spinal reconstructive surgery and were randomized to whether they received total parenteral nutrition postoperatively. Nutritional parameters included skin fold measurements, albumin, prealbumin, transferrin, and total lymphocyte count. Values for each were collected preoperatively and at regular intervals over the course of this prospective study. Patients assigned to the TPN group began to receive it on postoperative day #1 at 40 mL/hr, which was increased until nutritional requirements were met according to calculations. Patients not assigned to receive TPN received a postoperative course of intravenous fluids until tolerating a PO diet. Hu et al. found a greater incidence of infectious complications including pneumonia and urinary tract infections in patients who had depleted albumin and prealbumin levels versus that of patients with normal levels and a longer average hospital stay. No patients in this study had complications secondary to the administration of total parenteral nutrition.¹²

In their study, Lapp et al. randomized 46 patients to receive or not receive total parenteral nutrition after surgery for spinal deformity. Researchers measured nutritional parameters including albumin, prealbumin, transferrin, total protein, and absolute lymphocyte count before surgery and at regular intervals postoperatively until at least four of the five parameters were within ten percent of their preoperative baseline values. Based on the fact that surgical techniques are similar for treatment of complex trauma

as well as deformity, the data collected during this study may possibly be extrapolated to apply to the spinal cord injury based on the nature of physiologic insult whether it is caused by surgical intervention, a traumatic event or both. Patients receiving TPN postoperatively began to receive it postoperatively on the same day of surgery. These patients were compared to patients receiving intravenous fluids until they tolerated adequate oral fluids. Their results indicated that patients receiving TPN returned to their baseline regarding nutritional parameters faster than those not receiving TPN. In this study, there was no clinical difference between these two groups regarding major or minor complications. However, perioperative nutritional depletion has been shown to increase the chance of patient morbidity and nutrition related complications.¹³ Although no significant difference in complications were observed in this study, it does suggest a potential for the role of TPN in surgical spine patients at increased risk of nutritional depletion due to preoperative health status and surgical plan. At this time more research is likely necessary to clarify the role of TPN as it relates to the management of a spinal cord injury.

NUTRITIONAL MANAGEMENT OF THE CHRONIC SPINAL CORD INJURY PATIENT

The vast majority of spinal cord injury patients survive the acute course of their management post injury. However, depending on the level of neurologic injury, their lives may be drastically changed. Decreased neurologic function may result in decreased lean body mass secondary to muscular atrophy and a decreased activity level. Related to this difference in function and lifestyle, a common secondary complication of spinal cord injury is obesity. Obesity is the direct result of positive energy balance (more calories are taken in over the course of the day than are expended). As discussed earlier, total daily energy expenditure is comprised of three elements which have each been evaluated to varying degrees through research focused on the spinal cord injury patient.

As discussed earlier in this chapter and supported by Bucholz et al. in their 2004 study, the most quantitatively significant component of total daily energy expenditure is resting metabolic rate, accounting for approximately 65% of the total.¹⁴ If corrected for lean body mass, resting metabolic rate does not seem to differ drastically between the SCI patient and an able-bodied counterpart. However,

commonly used predictive equations of resting metabolic rate based on body mass tend to overestimate requirements for SCI patients by a range of 5–32% according to Bucholz et al. 2003.¹⁵ Based on current research it is estimated that the measured resting metabolic rate of the SCI patient tends to be 14–27% lower than that of an uninjured individual. This discrepancy seems to be predominantly the result of decreased lean body mass in the SCI patient since preliminary evidence suggests that neither the metabolic activity of the fat-free body nor the obligatory phase of the thermic effect of food is different (the influence of the facultative phase of the thermic effect of food has not been elucidated). Possible derangement in sympathetic activity depending on the level of neurologic injury may also play a role, although less significant than that of fat-free mass. Catecholamines have been found to also play a significant role in energy expenditure of the able-bodied individual. High level SCI is associated with markedly decreased sympathetic discharge. Studies by Jeon et al. and Bucholz et al. help to elucidate the interplay between resting metabolic rate and the sympathetic nervous system. Jeon and colleagues compared resting metabolic rate of seven men with complete tetraplegia with that of seven able-bodied control men and found the measured resting metabolic rate to be on average 27% lower in the SCI group. The authors incorporated plasma catecholamine and plasma leptin measurements into their study. They noted that plasma catecholamine concentrations (epinephrine and norepinephrine) were at least 300% lower in the SCI patients than the controls; and, plasma leptin levels were on average 207% higher in the SCI patients. The authors concluded that the lack of direct correlation in leptin level and resting metabolic rate in the SCI patients was possibly “due to the decentralization and impairment of the sympathetic nervous system, which may interrupt the pathway of leptin-mediated energy expenditure.”¹⁶ Along similar lines, Bucholz and colleagues produced a study comparing a cohort of paraplegic SCI patients with a cohort of able-bodied controls. Like Jeon’s study, the difference in resting metabolic rate was found to be quite low (less than 2%) when corrected for lean body mass. However, Bucholz did not find a difference in sympathetic nervous system activity via measurements of urinary metanephrine. “This may have been due to the fact that (their) subjects had paraplegia, whereas those of Jeon et al. had tetraplegia.... Thus, preliminary evidence indicates that the low RMR observed in paraplegia and tetraplegia appears to be due to reduced fat-free mass, and in tetraplegia, also to reduced sympathetic nervous system activity.”¹⁴

The second component to daily energy expenditure, previously discussed, is the thermic effect of food. A limited number of research studies have evaluated for a difference in this thermic effect between SCI patients and able-bodied controls. Although the first of the studies performed by Monroe and colleagues (*American Clinical Journal of Nutrition* 1998) indicated that the thermal effect of food was 26% lower in the SCI patient group, additional studies have shown no difference.¹⁷ Aksnes and colleagues as well as Bucholz and colleagues performed similar studies to further evaluate for difference. Of note, there were differences in design among these three studies. Monroe and colleagues followed their patients and controls over a 24 hour period in a respiratory chamber; and, subjects were provided a weight-maintenance diet. Aksnes and Bucholz administered a liquid meal and then measured the thermic effect of food for two hours post-prandially.¹⁸ Bucholz does take note that it is possible that differences may have become apparent had the study been extended beyond the two hour period. Regardless, the three studies provide data that support the idea that the early or obligatory phase of the thermic effect of food between individuals with and without spinal cord injury is not significantly different. Measuring the thermal effect of food presents difficulty because “the thermic effect of food is the least reproducible component of total daily energy expenditure because it is sensitive to physiologic factors, duration of measurement, and characteristics of the test meal.”¹⁹

Physical activity accounts for approximately 25–30% of total daily energy expenditure and, not surprisingly, multiple studies indicate that individuals with spinal cord injury have lower physical activity levels than those without, tetraplegia is associated with lower activity levels than paraplegia, and participation in athletic activities is decreased.^{15,20} Bucholz and colleagues recorded total daily energy expenditure over a three-day period and concluded in their study that “subjects” mean physical activity levels were (1) consistent with the World Health Organization’s definition of limited activity, (2) lower than levels previously reported in able-bodied adults, and (3) similar to those of adults with hereditary neuromuscular disease and cerebral palsy. This was the case despite 56% of participants having engaged in structured physical activity an average of 1.5 times during the observational period, for an average of 49 ± 31 minutes per session.”¹⁵ In this same study by Bucholz, researchers noted a significantly lower activity level (18% lower) in subjects with complete lesions than with incomplete lesions. Additionally, patients

with tetraplegia have a clear disadvantage regarding maintenance of daily physical activity levels.

Based on our understanding of these three components of total daily energy expenditure of the spinal cord injury patient, it can be extrapolated that caloric requirements should be estimated based on fat-free mass. Although additional studies are required to clarify the thermic effect of food, it can safely be recommended that SCI patients be encouraged to engage in physical activity regularly with a likely increase in frequency, intensity and duration when possible. Further research to clarify recommendations regarding the optimization of each of these three components of total daily energy expenditure would be beneficial as would efforts to clarify their relationship to neurologic level of injury.

In addition to obesity, osteoporosis is a major concern to management of the spinal cord injury patient. This form of osteoporosis differs from that of menopausal women due to the neurogenic component of its origin. Debate exists regarding its identification as well as management in this patient population and significant complications can result from its presence including long bone fractures.

Regarding the development of osteoporosis in the spinal cord injury patient, studies of bone metabolism indicate that there is a progressive elevation of bone resorption marker levels from the first week post injury onward, peaking between 3 and 6 months later. There has been an imbalance between these markers and bone formation markers which indicate the presence of bone loss. A decrease in bone mineral density is measureable from approximately 12 months onward; and, bone metabolism arrives at a new stable state at 16 months.²¹ Additionally, neurologic level determines extent of demineralization with tetraplegics affected in upper and lower extremities while the lower limbs of paraplegics are only generally affected.

Currently, the diagnosis of osteoporosis is based on determination of bone mineral density. It may be of benefit to measure bone density in regions commonly fractured in the spinal cord injury patient (including areas comprised of trabecular rather than cortical bone such as the distal femur or proximal tibia) as suggested by Shields in 2005. Biochemical markers, however, may offer information earlier in the process of the development of osteoporosis than measurement of bone mineral density. In their study, Maimon et al. revealed that bone mineral density testing in their cohort of seven patients (injured on average three

months prior to evaluation) did not detect a variation during this acute stage; however, biochemical markers of bone turnover were significantly increased including calciuria, decreased serum intact PTH, and $1.25(\text{OH})_2$ vitamin D levels.²² Therefore, blood and urine biochemical profiles may be useful in screening spinal cord injury patients for metabolic changes related to the development of osteoporosis. Craven et al. noted that frequently assayed markers of bone turnover including osteocalcin, N-telopeptide, and hydroxyprolinuria may be affected by mechanism of injury since many spinal cord injuries are associated with vertebral fracture.²³ The process of fracture healing can alter the levels of these markers for months, possibly making them less than ideal for use in the screening process for osteoporosis in the early period (first 3–6 months) following traumatic injury.

Regarding treatment of osteoporosis in the spinal cord injury patient population, the first step is to optimize nutritional status, and ensure that patients are receiving an adequate amount of vitamin D. According to Briot et al. the minimum recommended serum level of vitamin D is 30 ng/mL.²⁴ In their study Neumanaitis et al. concluded that inadequate or severely deficient levels of vitamin D-25(OH) were highly prevalent in patients with spinal cord injury admitted to an acute inpatient rehabilitation service; and, evaluation of serum vitamin D levels are recommended in patients with SCI since low levels may contribute to osteoporosis.²⁵ Bauman et al. recognized in their study that administration of a vitamin D analogue had a significant effect on the maintenance of leg bone mineral density in their cohort of 40 tetraplegic spinal cord injury patients.²⁶ Bauman et al. also noted in a study published in *The Journal of Spinal Cord Medicine* in 2011 that a daily prescription of 2000 IU of oral vitamin D(3) for 3 months safely raised the serum 25(OH)D levels into the normal range in persons with chronic SCI on 1.3 g of calcium daily.²⁷ Administration of vitamin D and calcium supplements are potentially helpful in the management of the compliant patient and are a recommended first step in the prevention of osteoporosis in this patient population.

Based on research reviewed, it appears that the role of bisphosphonate therapy in the treatment of neurogenic osteoporosis remains to be elucidated. According to Bryson's review of seven studies, "data were insufficient to recommend routine use of bisphosphonates for fracture prevention in spinal cord patients... Uniform bone density measurement sites with rigorous quality control and compliance monitoring are needed to improve reliability

of outcomes.”²⁸ Bryson’s criticisms of the studies she reviewed include sample size and confounding variables including inconsistency of calcium and vitamin D supplementation. Also, these studies tend to include a small number of patients and do not incorporate fracture outcomes. Regardless, certain studies have shown a decrease in the rate of decline in bone mineral density of patients with SCI with oral alendronate administered within ten days of SCI followed by weekly 70 mg doses for 12 months.²⁹ Additionally, research involving administration of a single 4 or 5 mg dose of zoledronic acid (given within ten to twelve weeks following injury) demonstrated attenuated bone loss at the proximal femur for 6 months and the distal femur for 12 months in the treatment group when compared with those administered a placebo.³⁰ Based on results such as these, bisphosphonate therapy may potentially aid the management of SCI patients suffering from osteoporosis; however, at this time, further research is necessary to clarify optimal treatment strategies and potential benefits to fracture prevention.

FUTURE DIRECTIONS

Levels of osteoprotegerin have been studied in spinal cord injury patients. Osteoprotegerin is part of the RANK/RANKL system and inhibits bone resorption. In their study, Morse et al. noted that serum osteoprotegerin levels correlated with severity of spinal cord injury and hypothesized that it might be possible to prevent post-SCI bone loss by the administering recombinant osteoprotegerin.³¹ Sclerostin is a protein synthesized by osteocytes which exerts regulatory effects on bone formation by osteoblasts.³² Recent trials (performed in monkeys) demonstrated that injection of antisclerostin antibody increased bone formation and density. Results of these studies also suggested that antisclerostin antibody had a positive effect on bone resistance and architecture.³³ Further research regarding the mechanism of bone loss in SCI patients and potential routes to directly limit such a process would be necessary to clarify treatment protocols and the relevance of medications such as antisclerostin antibody or recombinant osteoprotegerin. Valid treatment regimens for osteoporosis resulting from spinal cord injury may prove to be quite different than those developed for the management of post menopausal osteoporosis.

INTRODUCTION

The diagnosis of a spinal cord injury (SCI) brings with it a lifetime of additional challenges that go beyond the difficulties of muscle paralysis and sensory loss. Rehabilitation addresses the physical, medical, psychological, and social needs that arise as a result of this significant injury.

Early comprehensive interdisciplinary rehabilitation lays the foundation for improved functional outcomes in patients with SCI. The goals of rehabilitation following SCI are to maximize neurologic and functional recovery, to prevent secondary complications, and to assist the patient with community reintegration.

Rehabilitation specialists should be involved immediately following SCI.¹ In the first hours to days, emphasis should be on the acute management of the patient and stabilization of medical status. Early acute rehabilitation starts when the patient can participate fully in a rehabilitation program and concludes with successful community reintegration. For patients with traumatic SCI, early referral to a specialized acute care center reduces mortality, morbidity, and length of stay in acute care.^{2,3} Patients referred to integrated systems of SCI care have better functional outcomes, fewer secondary complications, and shorter hospitalizations.^{1,4-8} After the acute rehabilitation phase, regular long-term follow-up provides the ongoing ability to prevent and monitor secondary complications.

The interdisciplinary rehabilitation team consists of rehabilitation physicians, nurses, occupational and physical therapists, social workers, and psychologists working with patients and their families to maximize functional recovery. Other health care professionals may also be involved with patients throughout their rehabilitation.

After discharge into the community, regular, specialized continuing follow-up care is important to reduce the risks of secondary complications and to ensure the success of community reintegration. Patients with SCI have high rates of rehospitalization, particularly during the first year following discharge.^{9,10} The importance of follow-up is highlighted by the fact that the leading causes of rehospitalization include potentially preventable secondary complications such as urinary tract infections, pressure ulcers, and respiratory infections.

EPIDEMIOLOGY

Spinal cord injury can be categorized as traumatic or non-traumatic in origin. While traumatic SCI has been studied more than nontraumatic SCI, recent studies suggest that nontraumatic SCI may be more common than traumatic injuries in some regions.¹¹

The incidence of traumatic SCI varies from 15 per million in Australia and Western Europe to 35 per million in Canada and 39 per million in the United States.^{12,13}

The most common causes of traumatic injuries are motor vehicle collisions, falls, sports injuries, violence, self-harm, and work-related accidents. In older individuals, falls are the leading cause of traumatic SCI.¹⁴

Over time, the mean age of patients at time of injury has been increasing. Men have continued to be disproportionately affected, with 77.1% of new injuries occurring in males since 2000 in the United States. However, in elderly patients with SCI, the proportion of men to women affected is nearly equal.¹⁵ The prevalence of traumatic SCI has generally increased over time, which may reflect increasing life expectancy after SCI or increasing incidence.¹⁴

With regard to nontraumatic SCI, it appears that the incidence has been increasing over time.¹⁶ In a recent Australian cohort study, the proportion of nontraumatic SCI sampled from a national rehabilitation database was 62%.¹¹ Data is limited on frequency of etiology in nontraumatic SCI, but one study from South Korea demonstrated causes in order of frequency to be tumor, spinal stenosis, transverse myelitis, arteriovenous malformation, infection, spinal cord infarction, and epidural hemorrhage.¹⁶ Compared with traumatic SCI, those with a nontraumatic etiology tend to have a more equal distribution between sexes, older age at onset, and greater proportion of paraplegia, and have shorter in-patient rehabilitation admissions. At the same time, they appear to achieve a similar level of function on discharge from a rehabilitation program.¹¹

NEUROLOGIC ASSESSMENT IN SCI REHABILITATION

Neurologic assessment of patients with SCI is important for rehabilitation planning, for monitoring neurologic outcomes, and for predicting neurologic and functional prognosis. The neurologic assessment is performed using the International Standards for Neurological Classification of Spinal Cord Injury (ISNCSCI).¹⁷ The ISNCSCI examination is a focused neurologic examination consisting of three primary components: a sensory examination, a motor examination, and an autonomic standards assessment. Training modules for the examination are available online through the American Spinal Injury Association (ASIA) website (<http://asia-spinalinjury.org/learning>). Using the ISNCSCI standards, both a neurologic level and degree of injury completeness can be determined. The neurologic level of injury (NLI) is defined as the most caudal level with intact bilateral sensory and motor function. The degree of injury completeness is determined using the ASIA impairment scale (AIS) (Table 62.1).

Table 62.1: The ASIA impairment scale.¹⁷

ASIA impairment scale	Injury completeness	Definition
A	Complete	No sensory or motor sparing occurs in the sacral (S4–S5) segments
B	Sensory incomplete	Sensory function only is preserved in the sacral segments and no motor function is preserved more than three levels below the motor level on either side
C	Motor incomplete	Motor function is preserved below the neurological level* and more than half the muscles below the neurologic level of injury (NLI) are less than Grade 3 strength
D	Motor incomplete	Motor function is preserved below the neurological level* and at least half the muscles below the NLI are Grade 3 or above
E	Normal	In a patient with a spinal cord injury and prior deficits with a now completely normal International Standards for Neurological Classification of Spinal Cord Injury examination

*For patients to be assigned motor incomplete status they must have either voluntary anal contraction OR sacral sensory sparing with some preserved motor function more than three levels below the motor level on either side of the body.

The sensory examination includes bilateral assessment of dermatomes C2 through S4–S5, using both light touch and pinprick sensory modalities. The sensory level is the most caudal level with intact sensation in both modalities. The motor examination includes bilateral examination of one key muscle for each myotome from C5 to T1 and from L2 to S1. Motor grading is performed using the Medical Research Council grades from 0 to 5.

The motor level is the most caudal level with at least Grade 3 strength, as long as all myotomes above the level have Grade 5 strength. A rectal examination is performed to assess both for sensation of deep anal pressure and for voluntary anal contraction, which are important for determining whether the injury is sensory or motor sparing.^{17,18} A complete SCI is defined as an injury where there is no sparing in the lowest sacral segments as determined by the rectal examination.

Based on the guidelines of the Paralyzed Veterans of America, an initial neurological assessment should be performed as soon as possible, but within a maximum of 6 hours after a suspected SCI to confirm a diagnosis. Following this, a detailed examination using the ISNCSCI protocol should be performed between 72 hours from the time of injury to 7 days from the injury for prognostic purposes.¹⁹ Detailed assessments performed for prognosis at 48 hours may not have the same accuracy as a 72-hour examination due to the potential confounding presence of spinal shock.²⁰

Periodic reassessment is required until neurological recovery has reached a plateau. Typically, recovery after SCI is most rapid in the first 6 months post-injury. After 3–6 months, recovery speed slows significantly; however, there may be some recovery up to 2 years or even longer after injury.¹⁹

PROGNOSIS

Discussing prognosis with patients and their families is an important part of caring for individuals with SCI. Many patients will specifically want to know if they will walk again, but it is also valuable to have an appreciation of expected global outcomes by the level of injury. Most studies evaluating the use of the ISNCSCI standards for prognosis have been for patients with traumatic SCI. The use of the standards as a prognostic tool for nontraumatic SCI has not been as well studied. However, to date, studies comparing all-cause nontraumatic, ischemic, and even neoplastic SCI to traumatic SCI have not found significant differences in the degree of neurologic function on discharge from a rehabilitation unit. These studies have typically used statistical methods to correct for baseline differences in these populations, given that there are significantly lower rates of complete injuries in patients with a nontraumatic etiology compared to traumatic injuries.^{21–24}

The AIS, when determined at 72 hours post-injury, is very stable over time. In individuals categorized as AIS A at 72 hours, 80% will remain AIS A at the time of discharge from inpatient rehabilitation, with 10% converting to AIS B, and another 10% converting to AIS C.²⁰ Overall, the most important prognostic indicator is neurologic status at the time of initial assessment. Additional positive prognostic factors include younger age at time of injury, preservation of pinprick in sensory sparing injuries, and the length of time from injury to admission to a rehabilitation unit.^{20,22} Evidence of spinal cord hemorrhage on magnetic resonance imaging is a negative prognostic indicator for

Table 62.2: Prediction of functional ambulation by ASIA impairment scale.²⁰

ASIA impairment scale	Additional features	Percent functional ambulators at 1 year (%)
A	Cervical lesion	0
	Thoracic/lumbar lesion	5–8.5
B	Only light touch spared	0–33
	Light touch and pinprick spared	66–89
C	Less than 50 years old	71–91
	Greater than 50 years old	25–42
D	Less than 50 years old	100
	Greater than 50 years old	80–100

Source: Adapted from Scivoletto G, Di Donna V. Prediction of walking recovery after spinal cord injury. *Brain Res Bull.* 2009;78(1):43–51.

functional recovery and is associated with a greater proportion of complete injuries when found. Conversely, spinal cord edema tends to be correlated with a greater degree of recovery and is associated with incomplete injuries when it is present in the absence of hemorrhage. However, as the degree of edema increases, the prognosis worsens.²⁰

An overall prediction for recovery of ambulation by AIS grade is presented in Table 62.2. Functional ambulation is typically defined as walking a reasonable distance in and out of the home, and frequently will require the use of gait aids and lower extremity orthotic devices.

LATE DETERIORATION

It is important to continue to monitor patients with SCI to detect any evidence of neurologic deterioration. A decline in function or a progression of the NLI after an injury should raise concern about the possibility of spinal cord tethering or syringomyelia. Other causes of late neurologic deterioration include the development of peripheral nerve entrapments, such as carpal tunnel syndrome.¹⁹

Syringomyelia has an estimated prevalence of 21–28% within 30 years of the initial injury. However, only 1–9% of patients with syringomyelia post-SCI will be symptomatic, which mandates a careful clinical assessment to correlate symptoms to imaging findings. Symptoms include loss of

pain and temperature sensation, with relatively preserved proprioceptive and vibratory sensation, pain at or above the level of the lesion, and asymmetric progressive weakness. If the syringomyelia involves the brainstem, bulbar findings may be noted on examination of the cranial nerves. Typically, surgical intervention is considered in the context of progressive neurologic deterioration or pain associated with evidence of syringomyelia.²⁵

■ PAIN IN SCI

Pain is a frequent and significant complication of SCI. Prevalence estimates of pain after SCI have demonstrated a very wide range in the literature, from 26% to 96%, with 30–40% of SCI patients experiencing disabling pain.²⁶ The onset of pain is generally within the first 6–12 months after injury.²⁷ Patients with a low spinal cord or cauda equina lesion are more likely to report severe pain than others.²⁷

The International Classification of Spinal Cord Injury Pain proposes classifying pain in SCI as either neuropathic or nociceptive. Neuropathic pain is divided into at-level, below-level and other pain, whereas nociceptive pain is divided into somatic, visceral, and other pain.^{28,29} Although neuropathic pain is often due to the primary or secondary injury to the spinal cord, nociceptive pain may develop after the injury. In particular, musculoskeletal nociceptive pain involving the upper extremities is common, occurring in 58.5–72.7% of patients with SCI. Upper extremity pain may be attributed to chronic upper extremity overuse from wheelchair propulsion and transfers.²⁷

The management of pain after SCI can be approached with stepwise use of nonpharmacological, pharmacological, and even surgical measures. The initial step is taking a thorough pain history and establishing the etiology of the pain. It is particularly important to identify nociceptive pain sources, where an underlying disease needs to be treated in addition to treating the pain.

Other factors such as decubitus ulcers, infections, autonomic dysreflexia (AD), spasticity, mood or anxiety disorder, and renal calculi may worsen pain post-SCI.²⁷ In particular, it is important to consider a diagnosis of syringomyelia when a patient presents with new pain.³⁰

Nonpharmacological treatments such as hypnosis, visual imagery, and transcranial electrical or magnetic stimulation all have varying levels of evidence in the treatment of pain after SCI.^{27,31}

Gabapentinoids are the first-line pharmacologic treatment of neuropathic pain following SCI. While tricyclic antidepressants and serotonin–norepinephrine reuptake inhibitors are generally recommended for the treatment

of neuropathic pain, there is surprisingly limited evidence for their use in post-SCI neuropathic pain.^{27,30,32} Third- and fourth-line agents such as opioid analgesics and cannabinoids have some evidence for use following SCI. Cannabinoids may have promise in this patient group, given that other studies have demonstrated efficacy in other patient populations with central neuropathic pain.^{27,30} There is also evidence for the use of topical capsaicin, intrathecal clonidine in combination with morphine, intravenous ketamine, and the short-term use of lidocaine via subarachnoid lumbar catheter as treatments of post-SCI pain.²⁷

Finally, surgical approaches including spinal cord stimulation, dorsal longitudinal T-myelotomy, and dorsal rhizotomy/dorsal root entry zone (DREZ) procedures can be considered. There is little evidence to support the use of spinal cordotomy. There is no evidence to support the use of sympathectomy for the treatment of post-SCI pain.^{27,30}

■ BLADDER MANAGEMENT

Sexual Health

Renal failure was once the leading cause of death after SCI. Today, as a result of improvements in bladder care, renal failure accounts for only 3% of deaths post-SCI.³³ However, despite these gains, the importance of good neurogenic bladder management following SCI cannot be underestimated.

Almost all patients with SCI have neurogenic bladders. The type of bladder dysfunction depends on both the level and the completeness of injury. No matter what type of bladder dysfunction is present, the goals of management are the same: to preserve renal function, minimize urinary tract complications, and provide bladder management compatible with a patient's lifestyle.³³

During the acute phase post-injury, patients should have an indwelling urinary catheter placed until they are hemodynamically stable and no longer require strict fluid monitoring.¹ Once urinary output has stabilized, the preferred bladder management option is intermittent catheterization.³⁴ Intermittent catheterization should be performed every 4–6 hours, with target bladder volumes of <500 mL. Unfortunately, despite significant evidence that intermittent catheterization is the safest and healthiest long-term bladder management technique, compliance may often be an issue, with up to 42% of patients discontinuing this technique in the long-term.³⁵

Indwelling catheters should be considered in patients who are unable to manage their bladders with intermittent catheterization. Both urethral and suprapubic catheters are associated with increased rates of infection, as well as renal and bladder calculi.³³ Due to the increased risk of bladder cancer in patients with long-term indwelling catheters, patients with indwelling catheters should undergo regular screening cystoscopy.³⁶

Pharmacotherapy for patients is aimed at reducing incontinent episodes, while maintaining low bladder pressures, using agents such as anticholinergics, α -adrenergic antagonists, and intravesicular botulinum toxin type A.^{34,37}

Urinary tract infections are a frequent complication. Symptoms and signs include pyuria, discomfort or pain over the kidneys or bladder, dysuria, new onset incontinence, increased spasticity, cloudy urine with increased odor, malaise, lethargy, or a sense of unease.³³ Frequent, unexplained infections should prompt a search for a renal or bladder calculus.³⁸

Yearly evaluation of the upper and lower tracts is important in order to exclude changes in the urologic system that would indicate high-pressure voiding or renal calculi. Clinical history and symptoms may not correlate well to the degree of urologic dysfunction, and the goal of treatment is to keep bladder pressures below 40 cm H₂O in order to prevent long-term renal complications.³³ Urodynamics are an important component in monitoring response to treatment in patients and avoiding long-term complications. Up to two thirds of patients with an SCI demonstrate urologic deterioration on urodynamics in long-term follow-up, despite no change in their clinical status.³⁹

BOWEL MANAGEMENT

Sexual Health

Neurogenic bowel dysfunction is a frequent complication of SCI. Up to 95% of patients with SCI will have some degree of bowel dysfunction, and the same number of individuals will require at least one therapeutic intervention in order to defecate.^{40,41} This issue is severe enough to affect quality of life in 62% of individuals.⁴² The most common complications of bowel dysfunction include constipation, fecal impaction, hemorrhoids, and incontinent episodes.⁴⁰

Neurogenic bowel dysfunction can be divided into two different patterns. In injuries above the conus medullaris, there is a pattern of an upper motor neuron (UMN)

bowel characterized by increased colonic wall and anal tone, loss of cortical control of the external anal sphincter, and spastic external anal sphincter. This pattern is predominated by constipation and fecal retention. In injuries at the conus medullaris or cauda equina, there is a lower motor neuron (LMN) bowel with severely prolonged colonic transit time, atonic external anal sphincter, and absent control over the puborectalis and other levator ani muscles. This leads to constipation as well, but additionally carries a very high risk of fecal incontinence.

Several guidelines have been developed for the approach to bowel management, including guidelines by the Consortium for Spinal Cord Medicine and by the Multidisciplinary Association of Spinal Cord Injury Professionals.^{41,43} Both guidelines advocate a stepwise approach, beginning with history and physical examination to determine whether a patient has an UMN or LMN bowel pattern. Overall goals include the establishment of regular bowel care to allow for complete colonic evacuation and the prevention of incontinent episodes. General dietary recommendations start with an intake of 15 g of fiber per day and 40 mL/kg plus 500 mL of fluid daily.^{41,42}

For UMN bowel management, the approach typically utilizes local reflexes to initiate bowel movements with either digital stimulation or a chemical suppository.⁴² If evacuation is incomplete, manual disimpaction can be used to ensure a complete bowel movement. If stool consistency is too firm, oral laxatives can be added to the regimen. Although there is no clear body of evidence, often osmotic laxatives such as polyethylene glycol are used on a regular basis, with stimulant laxatives, such as bisacodyl or sennosides, used on an as-needed basis.^{4-6,41} For any patient who is prone to AD, local anesthetic gel should be applied to the anus several minutes prior to digital stimulation or insertion of suppositories to avoid triggering AD.^{41,43}

For an LMN bowel, the approach is manual disimpaction on a regular basis, ideally once daily or less, if continence can be maintained. Additional measures such as digital stimulation and the use of suppositories are typically not effective in this population due to a loss of local colonic reflexes.

For patients who consistently do not respond to conservative measures, more intensive approaches exist. Transanal irrigation and pulsed water irrigation both use water to remove stool from the descending colon. Both have shown efficacy in relieving constipation and incontinence in neurogenic bowel.⁴² For patients who do not tolerate noninvasive approaches, the Malone antegrade

continence enema procedure has demonstrated efficacy. This procedure creates an anastomosis between the appendix and cecum with a continent stoma, allowing tap water enemas to be inserted that stimulate colonic motility and emptying.⁴² There is also evidence for implanted sacral nerve root stimulators in otherwise refractory populations.⁴² Colostomy can be a safe and effective treatment of severely affected patients, and has been found to improve both quality of life and persistent perianal pressure ulcers based on case studies, pre-post studies, and retrospective reviews.⁴² However, a recent decision analysis study suggested that among the Malone procedure, sacral stimulation, and colostomy, the Malone procedure was the best option; this has yet to be confirmed with direct clinical trials.⁴⁴

Additional acute gastrointestinal complications of SCI include reflex ileus (4.6%), peptic ulcers (1.4%), and pancreatitis (2.2%). These are most common in the first month post-injury. Given the altered sensation in patients with SCI, these conditions may present atypically, and a high index of suspicion should be maintained in the event of nonspecific clinical deterioration.⁴¹

Respiratory Complications

Acute Injury

After acute SCI, the most common cardiovascular effect is acute hypotension with bradycardia. Initial management steps include IV fluid resuscitation, pressors and supportive care, until the period of neurogenic shock is over.¹

Venous Thromboembolism Prophylaxis

The incidence of early deep vein thrombosis (DVT) in acute SCI has been reported to be above 50% without treatment, with fatal pulmonary embolism (PE) occurring in as many as 5%.⁴⁵ While the highest risk of DVT is within the first 2 weeks following an acute SCI, DVT prophylaxis needs to continue throughout the rehabilitation phase. The clinical diagnosis of DVT is unreliable, and, accordingly, a high index of suspicion must be maintained.

Mechanical and pharmacological DVT prophylaxis should be initiated as early as possible. Mechanical compression devices are generally recommended for at least 2 weeks.^{46,1} Low-molecular-weight heparin (LMWH) should be initiated within 72 hours of injury in all patients

with SCI.^{1,47,48} Low-molecular-weight heparin should be held on the morning of surgery and resumed within 24 hours following surgery.⁴⁷ In motor complete injuries, LMWH should be continued at prophylactic doses for 8–12 weeks from the time of injury.^{45,48} In motor incomplete injuries, patients with AIS C injuries should receive LMWH for 8 weeks, and patients with AIS D injuries should receive anticoagulants for the length of their rehabilitation stay.⁴⁶ For patients who fail anticoagulant therapy, or who have a contraindication to anticoagulation, an inferior vena cava filter should be considered to prevent PE. Although studies are lacking, once a DVT is established, treatment is typically started with IV unfractionated heparin or full-dose LMWH. After transition to warfarin, full anticoagulation is maintained for 3–6 months.^{45,46}

Autonomic Dysreflexia

Autonomic dysfunction is common after SCI, thus leading to issues of AD and orthostatic hypotension (OH). AD is a medical emergency and must be treated aggressively. It occurs due to loss of central nervous system modulation of the sympathetic nervous system in individuals with SCI at the level of T6 or above. As a result, any noxious or inciting stimulus below the level of the injury may trigger excessive peripheral sympathetic outflow, leading to splanchnic vasoconstriction and a hypertensive emergency. An episode of AD is characterized by an elevation of blood pressure (BP) 20–30 mm Hg above baseline and is frequently associated with bradycardia due to unopposed vagal stimulation. It is important to recognize that AD may be occurring in a patient with a “normal” BP since resting systolic BP is between 90 and 110 mm Hg in patients with tetraplegia. Initial symptoms of AD may include headache, flushing and sweating above the level of the lesion, anxiety, nasal congestion, blurred vision, cardiac arrhythmias, and cool dry skin below the lesion. The consequences of untreated episodes of AD may be cerebral hemorrhage, cardiac complications, retinal detachment, seizures or death.^{49,50}

The treatment of AD is primarily directed at determining and eliminating the trigger of the episode. The most frequent cause of an episode is urinary retention or fecal impaction, and these should be checked first. Other causes are numerous and are included in Table 62.3.⁵⁰ After recognition of an episode, patients should be sat up in bed and have constrictive clothing loosened. BP and pulse should be monitored every 5 minutes while the bladder and bowel are being checked. If symptoms persist despite

Table 62.3: Causes of autonomic dysreflexia.⁵⁰

System	Causes
Genitourinary	Bladder distention Bladder or kidney stones Blocked catheter Catheterization Urologic instrumentation Detrusor sphincter dyssynergia Shock wave lithotripsy Urinary tract infection
Gastrointestinal	Appendicitis Bowel distention Bowel impaction Gallstones Gastric ulcers or gastritis GI instrumentation Hemorrhoids
Skin	Constrictive clothing, shoes, or appliances Contact with hard or sharp objects Blisters Burns, sunburn or frostbite Ingrown toenail Insect bites Pressure ulcers
Reproductive	Sexual intercourse Sexually transmitted infections Ejaculation Epididymitis Scrotal compression (sitting on scrotum) Electroejaculation and vibratory stimulation to induce ejaculation Menstruation Pregnancy Vaginitis
Other	Boosting (an episode of autonomic dysreflexia intentionally caused by an athlete with spinal cord injury in an attempt to enhance physical performance) Deep vein thrombosis or pulmonary embolism Excessive alcohol intake Excessive caffeine or other diuretic intake Fractures or other trauma Functional electrical stimulation Heterotopic bone Over-the-counter or prescribed stimulants Substance abuse Surgical or invasive diagnostic procedures

catheterization and bowel care, a search for other potential causes of AD needs to be undertaken. If systolic BP remains elevated above 150 mm Hg, a short-acting antihypertensive

should be considered. The most frequently used agents include nifedipine and topical or sublingual nitrates. In recent years, the use of nifedipine has been discouraged due to the risk of severe hypotension in other patient populations, although no adverse events have been reported in SCI patients. Other options include prazosin and captopril.⁴⁹⁻⁵¹

Orthostatic Hypotension

Orthostatic hypotension occurs in over 70% of patients, with 59% of them being symptomatic.⁵² It is defined as a 20 mm Hg drop in systolic BP or a 10 mm Hg drop in diastolic BP.⁴² Orthostatic hypotension is particularly common in the first month post-SCI, occurring in 74% of cervical and 20% of upper thoracic motor complete injuries.⁵³ First-line treatment is nonpharmacologic and includes increasing salt and fluid intake, avoiding diuretics, avoiding large infrequent meals, and using abdominal binders and compression stockings. In addition, maintaining the head of the bed at 20–30° may increase orthostatic tolerance over time.⁵² Although commonly recommended, many of these approaches have a relative absence of evidence.⁴² If symptomatic OH persists, pharmacological treatments include midodrine, an α -adrenergic agonist, and fludrocortisone, a mineralocorticoid.⁵² Overall, there is more evidence for the efficacy of midodrine, and it should be used in preference to fludrocortisone, but with careful attention to symptoms of AD.⁴²

Metabolic Syndrome

Metabolic syndrome and cardiovascular disease occur more frequently in patients with SCI than in healthy controls. On average, patients with SCI have lower lean body mass, higher glucose and insulin levels, and higher lipid levels.^{54,55} Overall, these effects may contribute to premature coronary artery disease and diabetes in patients with SCI.⁵⁶ The risk of developing cardiovascular disease is higher in patients with higher level injuries and complete injuries. In one study of patients with complete tetraplegia, 84% of asymptomatic patients had signs of coronary artery disease on nuclear medicine stress testing.⁵⁷ This highlights the need to engage patients with SCI in some form of lifelong aerobic exercise program. This can be challenging especially for patients with complete tetraplegia. Current physical activity guidelines for adults living with SCI suggest at least 20 minutes of moderate-vigorous aerobic activity two times per week, as well as strength training exercises two times per week.⁵⁸

Respiratory Complications

Long-term Complications

Respiratory complications, such as atelectasis, pneumonia and respiratory failure, account for a significant portion of chronic morbidity and mortality in SCI. There is a global decline in all lung volumes that is more pronounced progressively with higher level injuries.⁵⁹ Injuries at C5 and above cause diaphragmatic dysfunction that may lead to respiratory muscle fatigue and the need for mechanical ventilation. In patients with a level of injury at C2 and above, if there is preservation of the phrenic nerve and nucleus, diaphragmatic or phrenic nerve pacing may be an option in order to avoid long-term mechanical ventilation.^{59,60} For individuals with intact diaphragmatic function, there is impairment of the external intercostal and abdominal muscles, which are important for generating cough. Accordingly, even patients with paraplegia are at risk for long-term respiratory complications.⁵⁹

For individuals not requiring long-term invasive ventilation, there are several components to respiratory management. To clear secretions, and slow further decline in lung volumes, physical techniques are used. For secretions, postural drainage, manually assisted cough and insufflation-exsufflation devices may be used. To maintain lung volumes, lung volume recruitment techniques several times daily are important. These typically use a Bag-Valve-Mask to “stack” multiple breaths and expand lung volumes passively.⁵⁹

An additional chronic concern is the development of obstructive sleep apnea (OSA), which occurs at a rate of 25–45% in the SCI populations, compared to 2–4% in the general population.^{59,61} It appears that the increased rates of OSA may be due to weight gain due to inactivity, the use of antispasmodics such as baclofen, or the development of airway resistance because of reduced lung volumes. Patients with symptoms of OSA, such as morning headache and daytime somnolence, should be screened with overnight oximetry and formal sleep studies.⁵⁹

Spasticity

Long-term Complications

Up to 70% of patients with SCI develop spasticity severe enough to cause some degree of functional impairment.⁶² For up to 41% of patients, spasticity may be a major obstacle preventing community reintegration.⁶³ Spasticity has

been defined by Lance as “a motor disorder characterized by a velocity-dependent increase in tonic stretch reflexes (muscle tone) with exaggerated tendon jerks, resulting from hyperexcitability of the stretch reflex.”^{62,64} Despite this narrow definition, the term spasticity is often used to describe related findings that are a result of an UMN injury, such as hyperreflexia, clonus, prolonged cutaneous reflexes, and muscle spasms. It is this overall category of phenomenon that is of concern as it relates to patients with SCI.

Given that most individuals with SCI develop spasticity, it is important to consider whether there is a functional impairment caused by the increased tone. Problems associated with severe uncontrolled spasticity may include contractures, improper posture, pressure ulcers, and pain. However, mild spasticity may improve function by allowing patients with limited volitional motor function to transfer and stand and by lessening skeletal muscle atrophy.^{62,63}

Once spasticity is identified, it is important to rule out secondary causes of increased tone. Any noxious stimulus can manifest as an increase in spasticity. This includes constipation, pneumonia, urinary tract infection, ingrown toenails, pressure ulcers, menses and intra-abdominal pathology. Acute sepsis and syringomyelia should also be considered as potential causes of increased spasticity.⁶²

Treatment should be initiated if there are specific functional goals that may be achieved by reducing spasticity. Treatments cross the spectrum from noninvasive strategies, to pharmacotherapy, interventional and surgical approaches.

Noninvasive management includes regular stretching, physical activity, and therapeutic standing.⁶² Evidence does exist to support additional therapies such as electric passive cycling, assisted standing, and a neural facilitation activity approach.⁶³ Pharmacotherapeutic options include baclofen, tizanidine, dantrolene, benzodiazepines, gabapentinoids, and cannabinoids. Baclofen is a GABA analog that inhibits spinal neurons pre- and post-synaptically, and is generally considered the first-line agent for the treatment of spasticity in SCI.⁶³

Interventional options include focal chemodenervation using botulinum toxin or phenol.⁶³ Intrathecal baclofen therapy uses an implanted pump device to deliver very small doses of baclofen directly to the intrathecal space. It is considered for patients with severe, functionally limiting spasticity who do not respond to other treatments. Although complications may be severe in the event of

acute baclofen withdrawal, this occurs at a low rate, making it a very effective option for some patients.⁶³

Surgical options for patients include direct spinal cord stimulation via an epidural cord stimulator and spinal myelotomy. There is limited evidence from pre-post studies that spinal cord stimulation may provide spasticity relief for patients with intractable spasticity, but the duration of effect is not clear. Dorsal longitudinal T-myelotomy may result in reduced spasticity based on a single low-quality RCT and a single case series in patients with spasticity who did not respond to nonsurgical measures.⁶³ Other surgical interventions are aimed at reducing the orthopedic complications of spasticity. These include tendon lengthening, tendon plasty and osteotomy. These are typically performed for local spasticity that has not responded to other treatments, or for established contractures.⁶²

Pressure Ulcers

Long-term Complications

Pressure ulcers are estimated to be one of the most frequent and costly complications after SCI.⁶⁵ The annual incidence of pressure ulcers has been estimated at 20–31%, with ulcers occurring at any stage of injury from the acute to chronic phase.^{66,67} The primary inciting event in ulcer formation is often an elevation in pressure and shear forces. The forces of direct pressure cause ischemia by restricting flow through skin and soft tissue capillaries. Shear forces, which are applied in parallel to the affected tissue, also lead to ischemia, but affect penetrating vessels running perpendicular to the skin's surface. In addition to mechanical forces, patients with SCI may be more susceptible to ulceration due to biochemical alterations in skin and soft tissue structure.⁶⁷ Adding to this, patients with SCI have impaired sensation and often have compromised ability to shift the weight. Additional risk factors for the development of pressure ulcers include limitation in activity and mobility, smoking, complete injuries, bowel and bladder incontinence, muscle atrophy, poor nutritional status, male sex, lower education and socioeconomic status, comorbid medical conditions, anemia and hypoalbuminemia, spasticity and history of prior pressure ulcers.⁶⁶

The first sign of a pressure ulcer is a change in the skin appearance. However, underlying soft tissues such as muscle are actually more susceptible to ischemia. Accordingly, the injured skin may be thought of as the “tip of the iceberg,” which signals more significant damage below.⁶⁷ Table 62.4 outlines the National Pressure Ulcer Advisory

Table 62.4: National Pressure Ulcer Advisory Panel's (NPUAP) updated pressure ulcer staging system (NPUAP 2007).⁶⁸

Stage	Description
Deep tissue injury (suspected) stage	Purple or maroon localized area of discolored intact skin or blood-filled blister due to damage of underlying soft tissue from pressure and/or shear. The area may be preceded by tissue that is painful, firm, mushy, boggy, warmer or cooler as compared to adjacent tissue
Stage I	Intact skin with nonblanchable redness of a localized area usually over a bony prominence. Darkly pigmented skin may not have visible blanching; its color may differ from the surrounding area
Stage II	Partial-thickness loss of dermis presenting as a shallow open ulcer with a red pink wound bed, without slough. May also present as an intact or open/ruptured serum-filled blister
Stage III	Full-thickness tissue loss. Subcutaneous fat may be visible but bone, tendon or muscle are not exposed. Slough may be present but does not obscure the depth of tissue loss. May include undermining and tunneling
Stage IV	Full-thickness tissue loss with exposed bone, tendon, or muscle. Slough or eschar may be present on some parts of the wound bed. Often includes undermining and tunneling
Unstageable	Full-thickness tissue loss in which the base of the ulcer is covered by slough (yellow, tan, gray, green, or brown) and/or eschar (tan, brown, or black) in the wound bed

Panel grading system that is used to describe pressure ulcers.⁶⁸

Pressure relief is the mainstay of ulcer prevention and should be initiated as soon as possible once a patient is stabilized. The length of time a patient is on a spinal board is a risk factor for early pressure ulcer formation. Although randomized clinical trials have not been performed, expert opinion and observational studies endorse turning and repositioning all individuals with acute SCI every 2 hours.^{67,69} When turning a patient with SCI, it is important to avoid shear injuries. Patients should not be slid or dragged over surfaces; instead, lifts, sheets, and trapezes should be used. Pillows and foam wedges are used to pad bony prominences, and to prevent bony surfaces

from touching one another. Donut-type devices should be avoided.⁶⁷

The most vulnerable areas in SCI patients include the ischium, sacrum, coccyx, trochanters and heels. These areas should be inspected at least daily to allow for rapid detection of a forming ulcer.⁶⁷ As well, it is important to evaluate the degree of risk each patient has for the development of ulcers. The most commonly used scale for assessing this is the Braden Scale.⁶⁶

Mattresses, wheelchair cushions, commode chairs and vehicle cushions should be selected and tailored to the use of the individual patient. There is evidence that using a specialized seating clinic to make seating recommendations may help prevent ulcers from forming and should be strongly considered for all patients.⁶⁶ Even with appropriate pressure distribution surfaces, patients still need to do hourly weight shifts while using wheelchairs. Experimental evidence has shown that at least 1–2 minutes of pressure relief is needed to raise tissue oxygen levels in high-pressure areas. Although vertical lift offs for 12–30 seconds are often recommended, they are likely inadequate to relieve enough pressure.⁶⁶

If pressure ulcers become established despite optimal preventative measures, the treatment approach includes strict pressure relief, regular cleaning, adequate debridement, and the use of appropriate wound care products. The ulcer should be assessed at each dressing change and documented on a weekly basis to track healing. For stage III and IV ulcers that fail to heal, surgical treatment may be necessary with a muscle or musculocutaneous pedicle flap.⁶⁷ Of note, there are two high-quality randomized controlled trials that support the use of electrical stimulation to help wound healing in stage III and IV ulcers, and this should be considered as part of the approach to wound management.⁶⁶

Osteoporosis

Long-term Complications

Loss of bone density below the level of neurologic injury is an early and significant complication of SCI. The underlying mechanism for sublesional osteoporosis (SLOP) appears to be a combination of immobilization, lack of weight bearing and changes secondary to altered neurologic function.⁷⁰ Bone resorption and resulting hypercalciuria are evident within a few days of injury and reduced bone density is detectable on imaging by 6 weeks post-injury, before stabilizing by 1–2 years post-injury at

25–50% below average density for age-matched peers.^{71,72} Loss of bone density is associated with an increased risk of fragility fractures, particularly at the distal femur and proximal tibia.

Treatment of SLOP is targeted at both prevention of early bone loss and maintenance of bone density. For early prevention, there is some evidence of short-term efficacy with several bisphosphonates. In general, the earlier treatment is initiated after injury, the more effective it appears to be. There are fewer studies evaluating the maintenance of bone density after 1 year. As well, there is evidence that oral vitamin D may assist in the maintenance of lower extremity bone density.⁷³

There is limited evidence for the nonpharmacologic treatment of SLOP. Electrical stimulation and functional electrical stimulation (FES) cycle ergometry of at least 6 months duration may increase regional bone density over the areas stimulated. Passive standing and walking with lower extremity orthoses have been inconclusive with regard to their effects on bone density.⁷²

Heterotopic Ossification

Long-term Complications

Heterotopic ossification (HO) is the formation of abnormal bone in nonskeletal tissues. It can occur following any injury to the central nervous system including SCI.⁷⁴ Post-SCI, the incidence of HO varies across studies from 10% to 78%.⁷⁵ The most commonly affected joint is the hip, followed by the knee, with very rare involvement of other joints.⁷⁴ Consequences of HO following SCI include reduced joint mobility in 20–30% of patients and ankylosis in 3–8%.⁷⁶ Less frequent complications include decubitus ulcers, peripheral nerve entrapment, and, in rare cases, rhabdomyolysis.^{77,78}

Early HO has a nonspecific clinical presentation with local warmth, erythema, edema, limited range of motion, and low-grade fever.^{74–76} HO must be differentiated from other diagnoses such as cellulitis, septic arthritis, and deep venous thrombosis. Diagnostic imaging is important for confirming the diagnosis. A three-phase bone scan may show abnormalities as early as 2 weeks after symptom onset. While traditional radiographs are more specific, they may not show abnormalities until 3–6 weeks after symptom onset. Magnetic resonance imaging examination is the most sensitive modality, with changes present within 1–2 days of symptom onset. CT scans with 3D reconstruction may be useful for operative planning in patients with an established diagnosis.⁷⁴

Nonsteroidal anti-inflammatory drugs (NSAIDs) may reduce the development of HO when initiated within 3 weeks of SCI. There is no direct evidence that NSAIDs can treat HO once it has developed, but they are often used in this context. Etidronate has been shown to halt the progression of HO in patients with SCI in several studies.⁷⁵ Non-pharmacological management strategies include pulse low-intensity electromagnetic field therapy for prophylaxis of HO as well as radiotherapy. The role of physiotherapy has been somewhat controversial, based on a theoretical concern that aggressive passive range of motion could exacerbate ectopic bone formation. However, observational studies have shown passive and active range of motion to be safe in patients with HO.^{74,79}

Surgical excision is reserved for patients with functional impairment or secondary sequelae.⁷⁵ For most patients, surgery is planned for at least 1 year post-SCI, to allow for the ectopic bone to mature and stop growing further. Although there is no direct evidence to guide this, it is thought that recurrent HO is more likely while the ectopic bone is still metabolically active.⁷⁴

Sexual Health and Reproductive Function

Sexual function is impacted in most patients with SCI and should be addressed early following injury. A full medical assessment of the reproductive system should be made with particular attention to autonomic function, the preservation of sensation from T11-L2 and S2-S5, and the presence of anal contraction.⁸⁰

Reproductive function in men is usually affected by SCI. Erectile function, ejaculation and semen quality can all be impaired. Treatments of erectile dysfunction include PDE5 inhibitors, intracavernosal injections, and vacuum devices. Penile implants are used less often due to the potential complications, including erosion.⁸⁰ Semen retrieval methods such as vibrostimulation and electroejaculation may be used in men with SCI, but careful monitoring must be done due to the increased risk of AD.

Menstruation is often interrupted for several months post-SCI.⁸¹ However, once menses have resumed, fertility is thought to approach preinjury levels. Pregnancy in women with SCI requires increased medical oversight due to increased risk of urinary tract infections, pressure ulcers, increased immobility, decreased respiratory function and the risk of AD.⁸⁰

Mood

Long-term Complications

Depression is the most commonly studied psychological issue after SCI.⁸² Many patients experience reactive adjustment disorders following SCI, and prevalence rates of major depression can vary from 7% to 31% with suicide rates 2–6 times higher than those in the general population.^{83,84} The high prevalence of depression has a significant impact on function and quality of life. Complete injuries and medical comorbidities, including traumatic brain injury and substance use, increase the risk of depression.⁸⁵ Treatment consists of appropriate psychological support and antidepressant medications as required based on the patient's presentation.⁸⁴

Quality of Life and Community Reintegration

Long-term Complications

Quality of life is consistently reported as good or excellent in patients who are more than 5 years post-SCI.^{86,87} Interestingly, healthcare providers often underestimate the quality of life for patients living with SCI.⁸⁸ While life satisfaction is generally lower in patients with SCI during the first 2–5 years following injury, it increases in the long run.^{86,87} High functional independence, less pain, good social supports and high self-efficacy are all predictors of higher life satisfaction.⁸⁶ Increased levels of physical activity and exercise have both been linked to higher levels of physical and psychological well-being in individuals with SCI.⁸⁹

Environmental factors and social policies are also important when considering life satisfaction and community reintegration.⁸⁴ Physical accessibility in the community has improved in recent years with the introduction of curb cuts, universal design building codes and the creation of accessible public transit systems.⁹⁰ However, creating inclusive, accessible communities for people living with SCI depends on more than environmental factors. Patients need appropriate community resources including access to medical care, medical equipment and home care supports in order to achieve successful community reintegration.⁹¹

KEY POINTS

- Early referral to a specialized acute care center and integrated rehabilitation program reduces mortality, morbidity, and length of stay while improving functional outcomes.
- The mean age of patients with spinal cord injuries is increasing over time and nontraumatic spinal cord injuries are being recognized as an increasingly important cause of SCI.
- A standardized neurologic examination using the ISNCSCI is important for rehabilitation planning, for monitoring neurologic outcomes, and for predicting neurologic and functional prognosis.
- Secondary complications are an important cause of morbidity and mortality following SCI. Long-term follow-up is necessary in order to reduce the risk of rehospitalizations due to preventable secondary complications such as pressure ulcers and urinary tract infections.
- Quality of life is consistently reported as good or excellent in patients who are more than 5 years post-SCI, but health care providers often underestimate the quality of life for patients living with SCI.

INTRODUCTION

Anterior and lateral exposures to the lumbosacral spine are used in Anterior Lumbar Interbody Fusion procedures to gain exposure to the vertebral bodies and intervertebral disks. The three major exposure techniques are the anterior retroperitoneal, transperitoneal, and lateral transpsoas. Each approach has associated advantages, disadvantages, and specific uses. The shared goal is to gain visualization in order to perform the appropriate procedure to correct spinal pathology.

In general, the pathology helps dictate which approach may be most suitable. Pathology affecting the vertebral bodies calls for an anterior or lateral exposure, while pathology within the spinal canal is more readily managed using a posterior approach depending on the spinal level.¹ The exposure that grants the surgeon the best visualization should be strongly considered. Once an approach is selected there are other variables to consider. A left-sided approach is often selected in the lumbar spine so that the thin-walled inferior vena cava is avoided. Although the retroperitoneal technique is favored in the lumbar spine, the transperitoneal approach is also used, albeit less frequently, when the retroperitoneal approach is contraindicated. It is often used in the setting of revision surgery especially for procedures involving the L5-S1 level. Direct access to the anterior and middle columns of the lumbar spine is gained using anterior exposure techniques. There are many factors involved in selecting

the optimal approach, and this decision is typically made on a case by case basis.

CLINICALLY RELEVANT REGIONAL ANATOMY

Abdominal Wall

Regardless of the approach, detailed knowledge of the anatomy of the lumbar and sacral spine is necessary in order to decrease the risk of complications and to achieve optimal results. During the approach to the anterior lumbar spine, the outermost layers include the skin, fat, and subcutaneous tissue. The abdominal musculature consists of the transversus abdominis, and internal and external oblique muscles with contributing fascial extensions that coalesce to form the anterior and posterior rectus sheath.² These are the extrinsic muscles located adjacent to the spine along with the rectus abdominis, latissimus dorsi, and serratus dorsalis caudalis muscles (Fig. 63.1). Running ventrally and laterally the rectus abdominis muscle extends from the pubis to the costal cartilages of ribs 5–7 and the xiphoid process of the sternum. The internal and external obliques, along with the transversalis muscles, emerge from the ribs and thoracodorsal fascia and insert caudally at the iliac crest and medially at the linea alba.² The latissimus dorsi muscle originates from the sacrum, dorsal iliac crest, spinous processes of vertebra T7–L5, and the 10th–12th ribs. The serratus dorsalis caudalis muscle

Fig. 63.1: Coronal sections through thoracoabdominal musculature above and below umbilicus.

Fig. 63.2: Psoas muscle relationships to lumbar and sacral vertebrae and pelvis.

has its origin at the lower four ribs and continues on a medial course to its insertion at the thoracolumbar fascia. The intrinsic spinal muscles include the erector spinae, quadratus lumborum, multifidus, and the deep muscles.² Three muscles make up the erector spinae; these are the iliocostalis, longissimus, and spinalis muscles from lateral to medial. The psoas major muscle lays ventrolateral to the lumbar spine. Posteriorly, originating from the lateral portion of the vertebral bodies and transverse processes of L1-5, the psoas muscle continues through the pelvis and into the thigh (Fig. 63.2).² The quadratus lumborum and iliocostalis muscles are located superiorly and inferiorly in relation to the psoas muscle, respectively.⁵ The diaphragm inserts into L3 via the right crus and L2 via the left crus. The right crus must be released to access L3/4, and both must be released to expose L2/3.⁵

Vascular

The abdominal aorta begins at the level of the T12-L1 intervertebral disc at the aortic hiatus of the diaphragm and divides into the common iliac arteries around L4-5.² The location of the aortic bifurcation can vary in individuals.

The aorta is located on the left of the vena cava, which runs along the right side of the spine. The common iliac veins unite at the fifth lumbar vertebra to form the inferior vena cava.² In general, the vena cava bifurcation is superior to the L5-S1 level, and on the right side of the L5 vertebral body. The anatomy of the iliolumbar vein is of great importance to exposure of the L4/5 disc space because it can interfere with the mobilization of the iliac vessels from the anterior spine. In most cases, the iliolumbar vein branches off the common iliac vein posteriorly at the level of L5⁵ and is generally located within 2 cm of L4/5.² However, this point can vary considerably.² There is a great deal of anatomic variations in both the aortic and caval bifurcations, which can potentially complicate cases (Fig. 63.3).²

Lymphatics

The lymphatic system runs along the lateral aspect of the spine entwined with the vasculature.⁵ The association of the lymphatics with the vasculature system and the psoas muscle can lead to lymphatic vessel disruption, especially during procedures involving the exposure of levels L4/5 and higher.⁵

Fig. 63.3: Variations of the superior hypogastric plexus.

Fig. 63.4: Anatomic representation of the lumbar plexus.

Nerves

It is of great importance to possess detailed knowledge of the nerves surrounding the lumbar and sacral spine. The lumbar plexus is formed lateral to the intervertebral foramina of L1–L4, passes through the psoas muscle, and gives rise to the obturator and femoral nerves (L2, L3, and

L4).² The ilioinguinal nerve, iliohypogastric nerve, and lateral femoral cutaneous nerve course laterally to the psoas muscle.⁵ The genitofemoral nerve (L1 and L2) lies on the psoas muscle anteriorly, and the sympathetic chain lies just lateral to both the vertebral bodies and the psoas⁵ (Fig. 63.4). The sympathetic chain and parasympathetic nerves form plexuses and ganglia that run ventrally along

Fig. 63.5: Anatomic representation of the ilium relative to the lumbar spine.

the aorta.² Formation of the superior hypogastric plexus occurs at the level of L5 where it courses inferiorly in variable forms, ranging from a distinct nerve to a diffuse plexus.⁵ The plexus forms the right and left hypogastric nerves, which supply the pelvis with sympathetic innervation.⁵ Injury to this nerve can lead to retrograde ejaculation in men.⁵

Retroperitoneal Structures

Dorsal to the peritoneum, the kidneys lie beside the vertebral column.² The ureter is also retroperitoneal and adherent to the peritoneum. Therefore, excessive dissection should be avoided to prevent devascularization during mobilization of the ureter.

Iliac Crest

The rim of the ilium usually lies at the level of L4, although this may vary (Fig. 63.5).^{9,10} The height of the iliac crest is an important consideration for the lateral transposas approach. A high-riding iliac crest can inhibit lateral access to the L4/5 interspace limiting the success of this procedure.^{10,11}

SURGICAL APPROACHES

Considerations

The following general considerations typically apply to a given exposure. Preoperative MRI may be performed to

Fig. 63.6: Typical incisions through the abdominal wall.

visualize the precise location of the bifurcation of the great vessels in order to help the access surgeon plan the approach. A pulse oximeter placed on the patient's left and right first toe is useful to monitor blood flow and possible ischemia.⁴ Care should be taken to make sure that there is adequate overhead lighting, and the use of headlamps or self-illuminating retractors may be considered. The skin incision made for anterior exposures can differ based on the vertebral level, experience of the access surgeon, the number of operative levels, prior abdominal surgery, patient obesity, and the procedure being performed. Transverse incisions are used for single vertebral-level procedures, while a vertical midline incision is made for multilevel procedures where increased working space is required (Fig. 63.6).⁴ A larger vertical incision can complicate any future revision surgery due to increased interruption of retroperitoneal planes and greater scar tissue formation. If autologous bone graft is needed, it should be harvested prior to the placement of the retractors.² The use of radiolucent components such as retractors blades can be helpful owing to the number of intraoperative radiographs that must be taken to ensure correct positioning and the protection of delicate surrounding structures. A table-held retractor system is important as it exerts a constant pressure on the abdomen, increasing the space and visualization and decreasing time-consuming readjustments. Retraction time should be minimized to avoid damage to vessels.¹² In the case of a multilevel procedure, the retractors should be set up for each level and relocated for the subsequent level to minimize stretching of anterior vessels. To help reduce the chance of an ileus, gastric decompression and stool softeners are recommended.⁸

Indications and Contraindications

Procedures such as discectomy, interbody fusion, and corpectomy require access to the lumbosacral spine to treat a wide variety of conditions arising from trauma, infection, tumor, degenerative disc disease, recurrent disc herniation, spondylolisthesis, deformity, and instability. Relative contraindications for these procedures include infections of the abdomen/pelvis, severe obesity, calcifications of the aortic bifurcation, pelvic inflammatory disease, and previous anterior exposure at the same level. Procedures involving high-grade spondylolisthesis and deformities measuring $>30^\circ$ of rotation should not be performed with a transpoas approach due to limited ability for deformity correction and positioning challenges, respectively.⁶ The direct lateral transpoas approach is also contraindicated in patients who have extensive retroperitoneal scarring.⁵

Anterior

Retroperitoneal Technique

The patient is placed in a supine position. Trendelenburg positioning may help shift the abdominal contents cranially to aid the access surgeon with the exposure. The ipsilateral hip should be flexed to relax the psoas muscle. Complete muscle relaxation should be achieved by anesthesia to prevent displacement of the retractors due to muscle tension during the procedure.⁴ The level of the incision may be assessed with lateral fluoroscopy, which can provide clues as to which angle will provide the best visualization (Figs. 63.7A and B). Approach from the left side is preferable for avoiding the liver and inferior vena cava, whereas the thicker walled aorta is retracted instead.² The incision is made in a lateral orientation starting between anatomical landmarks of the umbilicus and the pubic symphysis.³ Next, electrocautery is used to carefully dissect the subcutaneous tissue, fascia, and muscles until the retroperitoneal space has been accessed (Fig. 63.8). The exposure proceeds in-line with the skin incision, and the external oblique, internal oblique, transversus abdominis, and transversalis fascia are split in succession until they have been divided (Fig. 63.9).³ While dissecting the left rectus muscle, attention must be paid to preserving the superficial epigastric vessels. The peritoneum is carefully reflected anteriorly by blunt dissection with a finger along the inferior edge of the posterior rectus sheath to gain access to the retroperitoneal space (Fig. 63.10). The ureter and retroperitoneal fat are also reflected anteriorly. The next step is to palpate the vertebral bodies and safely move

Figs. 63.7A and B: Use of fluoroscopy in the retroperitoneal approach (A) in positioning of lateral skin incision (B).

Fig. 63.8: Dissection exposure to access the retroperitoneal space.

Fig. 63.9: Axial view of the starting level of dissection.

the great vessels anterior to the spine and out of the field using a Deaver retractor. At approximately the L4 level the common iliac arteries and veins bifurcate and must be retracted carefully to expose the anterior portion of

Fig. 63.10: Axial view of the appropriate retroperitoneal plane of dissection to the lumbosacral spine.

Fig. 63.12: Sacral vessels overlying L5 vertebral body.

the vertebral bodies.⁶ When approaching the L4/5 level, it is important to ligate and transect the iliolumbar vein to reduce the risk of injury to this vessel. Care must be taken to avoid violation of the lumbosacral plexus lying in close proximity to the iliolumbar vein. The landmark for the lumbosacral region is the sacral promontory, which is found just below the aortic bifurcation (Fig. 63.11). The vasculature overlying the L5 vertebral body includes the common iliac artery and vein anteriorly, the internal iliac

Fig. 63.11: Vasculature overlying the L5 vertebral body.

artery and vein just posterior, and the iliolumbar vein most posterior (Figs. 63.4 and 63.12). These vessels must be retracted gently to achieve exposure of the vertebral body and intervertebral disks. The external iliac artery should be mobilized distally in order to reduce longitudinal stress on the vessel and thereby decrease the risk of thrombosis.³ Using a Kittner dissector, the appropriate disc space can be mobilized and the middle sacral vessels ligated.⁴ The exposure should now yield an open visual field to the anterior portion of the lumbar spine sufficient for managing the affected pathology.

Transperitoneal Technique

Antibiotics should be administered preoperatively, and bowel preparation is often given the day before the surgical procedure.⁴ The patient is placed in the supine position with the sacrum elevated. Adjusting the operating table into the Trendelenburg position shifts the abdominal contents toward the upper abdomen. Two incisions are possible, midline and a transverse, and fluoroscopy may be used to aid in the selection of the incision site.³ If using a midline incision, start inferior to the umbilicus; however, this incision can be extended proximally, if necessary, avoiding the umbilicus. The patient may prefer the transverse incision for cosmetic reasons. Proceeding with the transverse incision, the rectus sheath must be transected and the rectus abdominis muscle divided.³ Joined together are the posterior rectus sheath, abdominal fascia, and peritoneum. By opening both the rectus

sheath and abdominal fascia, the posterior peritoneum may be incised. As a result, access is granted into the peritoneum. Progressing through the peritoneum should be done carefully as to not disrupt any segment of fragile bowel.⁶ The abdominal contents are retracted rostrally while proceeding deeper. The sacral promontory may now be palpated as an anatomical landmark for the aortic bifurcation just superior to it. The underlying tissue may be coated with a layer of saline solution at this point in order to make identification of smaller structures easier. The common iliac artery may be retracted proximal to the bifurcation to augment the exposure.² Next, the middle sacral artery and hypogastric plexus must be retracted laterally. If the left common iliac vein limits access to the L5-S1 region, it must be carefully mobilized before addressing the spinal pathology (*see* Fig. 63.10). It is best to perform longitudinal blunt dissection in this region to mobilize the smaller vessels. If bleeding occurs, monopolar electrocautery is ill advised due to possible damage to the hypogastric plexus; instead, a sponge and direct finger pressure should be applied followed by suture ligation or bipolar cauterization.⁴ Once the vasculature anterior to the vertebral body has been appropriately managed, the pathology can be corrected. After completion of the surgical procedure, the posterior peritoneum is closed using absorbable sutures and the abdominal contents are returned. The bowel and omentum are then replaced, and the rectus, subcutaneous tissue, and skin are closed in multiple layers.

Fig. 63.13: Skin incisions in the transpsoas approach.

Lateral

The current technique most commonly used in the United States to access the lateral aspect of the lumbosacral spine is the minimally invasive lateral transpsoas approach, first described as the Extreme Lateral Interbody Fusion by Ozgur et al.⁵ The uses for this approach include, but are not limited to, lumbar fusion to treat low-grade spondylolisthesis, and adult degenerative lumbar scoliosis.⁶ This approach preserves both the anterior and posterior longitudinal ligaments. The lateral approach is used by some surgeons to treat older patients on the basis of involving significantly less visceral and vascular dissection for exposure. Unlike the previous two approaches described, the anesthesia administered should not include a muscle relaxant or paralytic agent beyond the initial intubation because muscle twitch is required for electromyogram (EMG) testing of the psoas muscle during the insertion of dilators.³

Transpsoas Technique

An early description of a minimally invasive lateral approach included two incisions, a direct lateral incision in the flank over the intervertebral disc and a posterolateral incision just lateral to the paraspinal muscles (Fig. 63.13). The patient is placed in the lateral decubitus position under general endotracheal anesthesia (Fig. 63.14). The patient should be secured in place for the procedure with pillows supporting the midsection to increase the width between the 12th rib and the anterior superior iliac crest,

Fig. 63.14: Lateral decubitus patient positioning.

thus creating a larger window for exposure.¹⁴ The top leg should be flexed so that the psoas muscle is relaxed. In approaching the L2/3 disc space, the 12th rib may need to be resected. For exposing the L1/2 disc, an intercostal approach between the 11th and 12th ribs is utilized. The ideal incision site can be determined using fluoroscopy and marked on the skin accordingly (Fig. 63.15). A second incision is made posterior to the first, which will facilitate blunt dissection between the erector spinae and the oblique musculature (Fig. 63.16). With an index finger, the surgeon can feel through the posterolateral muscle down to the lumbodorsal fascia, which is opened with little resistance to access the retroperitoneal space. Next, the surgeon orients his or her finger superficially toward the incision

site to open a working channel for the dilator trajectory.¹⁴ Using an index finger, the surgeon guides the dilators through the direct lateral incision down to the surface of the psoas (Figs. 63.17A to D). Electromyogram monitoring is used while the psoas muscle is carefully divided to help prevent damage to the lumbar plexus contained within the psoas muscle. The psoas fibers are gently divided taking care not to damage the lumbar plexus or genitofemoral nerve.⁵ The initial dilator is secured using a Kirschner wire passed through the dilator and into the disc space, which is subsequently followed by larger dilators to gradually increase the opening. Once the psoas has been divided, the dilators should be at the level of the vertebral body. The expandable retractor is then placed over the dilators

Fig. 63.15: Use of fluoroscopy to aid in exposure of the L1/2 disc in the transpsoas approach.

Fig. 63.16: Axial view of the plane of dissection between the erector spinae and the oblique musculature.

Figs. 63.17A to D: Using an index finger, the surgeon guides the dilator through the direct lateral incision down to the surface of the psoas.

and locked in place to the surgical table. The dilators are removed to access the disc space, and a lateral radiograph may be taken to confirm positioning. The exposure is complete and the remainder of the procedure may be performed.

Complications

There is potential for a wide variety of complications with anterior lumbar exposures. The retroperitoneal and transperitoneal approaches have similar complication profiles. Awareness of prior surgical procedures or disease processes of the lower abdomen is vital as this can make manipulating tissue planes more challenging. Some testicular pain postoperatively has been reported in male patients with past hernia repairs.⁵ During the dissection and mobilization stages, minimizing force can help protect structures such as the ureter.⁵ Mobilizing the gonadal vessels and the left ureter *en bloc* with the peritoneum also can help protect the ureter.⁵ Tears in the peritoneum can occur, and primary repair is encouraged to decrease the potential of intestinal injury.⁵ In the case of an injury leading to the exposure of luminal contents, the surgeon should consider deferring spinal intervention until healed.⁵ A frequently encountered difficulty is the retraction of the great vessels anterior to the spinal column, especially at the L4/5 level. The variable location of the iliolumbar vein places this vessel at risk for avulsion during an L4/5 exposure, and this can cause a significant venous bleed.⁵ Vessels can sustain injury during retraction or from manual mobilization. Increased retraction time increases the risk of damage to blood vessels. Because of the location of the great vessels anterior to the lumbar spine, ligation of the inferior vena cava and common iliac veins above and below the lesion can be performed quickly as a last resort if bleeding cannot be otherwise controlled in order to prevent catastrophic morbidity and mortality. The risk for thromboembolic events may be increased in patients with baseline atherosclerosis.⁵ Injuries to the lymphatic system can occur, but typically are not significant. In the rare event of a lymphocele, percutaneous drainage is recommended.⁵ Infectious complications are rare, but when they occur they should be treated with antibiotics and drainage.⁵ Deep space infections are also rare, occurring in <1% of patients.¹² One of the most feared complications is injury to the hypogastric nerve, which may lead to retrograde ejaculation in men.⁵ The use of electrocautery should be minimized in the anterior lumbar region due to an increased risk of damage to the superior hypogastric plexus.

It has been documented that the autonomic plexus is vulnerable to injury due to increased heat, and the resulting lesion can also cause retrograde ejaculation.⁷ Both retroperitoneal and transperitoneal approaches can result in hypogastric plexus damage; however, it has been reported that there is a 10-fold increase in the incidence of retrograde ejaculation with a transperitoneal approach.¹³ This complication may be avoided with careful dissection practices.

Complications secondary to the minimally invasive lateral approach, a relatively new procedure, have been reported but the literature is still developing in this regard. To minimize risk of complications such as numbness of the lateral thigh, minimal retraction is used.¹ It is important to have clear images on fluoroscopy for the transpoas approach, and intraoperative radiographs should be taken frequently to make sure the correct alignment is being maintained.⁵ When the exposed area has not been properly irrigated, artifacts may affect intraoperative fluoroscopy. Although this approach effectively provides access to spinal levels from T7 to L4-L5, it may be difficult to reach L4/5 with a high-riding iliac crest, and current technology does not allow this approach to treat spinal disease at L5-S1.¹

DISCUSSION

There are various approaches to choose from for exposing the lumbosacral spine. Selecting one requires careful review of the strengths and potential risks of each approach as well as the intricacies of the case. An anterior exposure is best suited for situations where broad visualization of the lumbar spine is required. The retroperitoneal approach can probably be considered the gold standard because of a lower complication rate, decreased damage to viscera and great vessels, broad exposure, and less abdominal wall tissue dissection. Although the transperitoneal approach may be simpler for exposure of the L5-S1 disc space, it is not commonly used because of the associated complication profile. There is a higher complication rate than with the retroperitoneal approach,⁵ and most notably there is an increased risk of hypogastric plexus damage that can lead to retrograde ejaculation.⁵ Therefore, this approach should not be utilized for young male patients when possible and used mainly for revision surgeries or in patients with preexisting retroperitoneal scarring from prior surgery or radiation.⁵

The minimally invasive direct lateral transpoas approach can provide excellent exposure to the lumbar spine, and some authors have described a favorable complication

profile compared with traditional open techniques. When compared with the anterior approaches described, there is decreased dissection and damage to surrounding tissues, less risk of damage to the great vessels and viscera, reduced blood loss, lower operative time, and no need for an access surgeon. Whereas a large body habitus can be problematic in other approaches, this approach places the patient in a lateral decubitus position, which mobilizes the abdomen away from the spine thereby aiding in opening the retroperitoneal space.¹⁴ However, significant limitations include the inability to access the L4/5 disc space in the case of a high-riding iliac crest, the inability to access L5/S1, and complications related to lumbar plexus injury, including postoperative sensory and motor deficits.¹⁴

CONCLUSION

In some cases, spinal pathology and the location thereof will dictate the best surgical approach, although the experience and approach of the surgeon are also critical elements. The anterior transperitoneal approach should be used mainly for revision surgery or with extensive prior retroperitoneal surgery. In the lower lumbar region, if the spinal disease can be attended to unilaterally, the retroperitoneal approach is preferred.¹ The lateral transpsoas approach cannot be used below the L4-L5 level due to obstruction by the iliac crest, and many surgeons avoid the use of this approach at the L4-L5 level because of descriptions of increased neurologic complication rate at this spinal level.

Anterior Exposure

Retroperitoneal Approach

Advantages

- Lower complication rate
- Decreased risk to viscera and great vessels compared with transperitoneal approach
- Better cosmesis
- Less abdominal wall tissue dissection
- Broad exposure to lumbar spine.

Disadvantages

- May be more difficult with retroperitoneal scarring from infection, radiation, or prior surgery.

Transperitoneal Approach

Advantage

- Easily visualizes the L5-S1 disc space.

Disadvantages

- Used less often, and therefore less surgeon experience
- Requires manipulation of peritoneal contents
- Increased risk of injury to the sympathetic chain and hypogastric plexus
- Higher complication rate
- Reserved mainly for revision surgeries or with pre-existing retroperitoneal damage.

Lateral Exposure

Lateral Transpsoas Approach

Advantages

- Access surgeon is often not required
- Less dissection and damage to abdominal structures
- Decreased need to retract the peritoneum and great vessels

Disadvantages

- Anatomical barriers at iliac crest inferiorly preclude access to L5-S1
- Careful EMG monitoring of the psoas muscle required to prevent injury during dissection and to prevent injury to the lumbosacral plexus
- Exposure to intraoperative fluoroscopy
- Decreased deficit correction compared with other techniques.

KEY POINTS

- Pathology dictates which approach (anterior vs lateral) and which exposure (open vs laparoscopic) are utilized.
- The anterior retroperitoneal approach is the standard, due to decreased complication rate, better cosmesis, and less abdominal wall dissection in providing exposure to the lumbar spine relative to the transperitoneal approach.
- Plan preoperatively and review the specifics of the case and the approach with the access surgeon. Providing an adequate exposure safely and efficiently, while avoiding overdissection and maintaining a safe retraction, is paramount.
- Lateral interbody fusion is a procedure used for the correction of degenerative scoliosis, multilevel fusions, or adjacent segment degeneration. This can be performed in a minimally invasive fashion that does not require anterior access and may shorten recovery time.
- The lateral approach to the spine requires splitting the psoas muscle, and neurologic monitoring is

required to decrease the risk of nerve injury. Because of the smaller incision and decreased tissue dissection, there is a greater reliance on imaging and exposure to radiation from fluoroscopy.

INTRODUCTION

Posterior approaches to the lumbosacral spine are relevant for surgical treatment of many spinal pathologies, including traumatic, degenerative, vascular, congenital, and neoplastic disorders. Posterior techniques are not only the most common surgical exposure of the lumbosacral spine but are also fundamental techniques for most spinal surgeons. Posterior approaches can be classified into either midline or paraspinal approaches, referring to the laterality of the surgical approach, in combination with a macrosurgical and/or a microsurgical exposure.¹ Some examples of macro- and microsurgical midline posterior approaches to the lumbosacral spine include laminotomy, laminectomy, medial and lateral facetectomy, pedicle subtraction osteotomy, Smith-Petersen osteotomy, and en bloc spondylectomy.²⁻⁹ Using a historical perspective, this chapter briefly reviews the concepts of conventional and minimally invasive posterior lumbosacral approaches with regard to macro- and microsurgical exposures, and the progression of surgical methods from rigid fusion to dynamic stabilization in combination with the development of minimally invasive spinal surgery (MISS).

SIGNIFICANCE OF MUSCULOTENDINOUS ANATOMY OF THE LUMBOSACRAL SPINE

Conventional midline approaches to the spine are relatively straightforward and require relatively little anatomical

consideration. They allow direct access to all lumbosacral levels. However, midline macrosurgical exposures carry with them serious limitations including sacrificing or compromising of major stabilizing elements of the posterior spine, especially of the three major muscles: multifidus, longissimus, and iliocostalis (Fig. 64.1).^{10,11} Among them, the multifidus muscle is especially relevant because it has a fundamental function as a spinal stabilizer and has a unique architecture.¹¹⁻¹⁷ For instance, Macintosh et al¹⁵ described that only the multifidus muscle is present in the region of the L5 vertebra, which is covered by the erector spinae aponeurosis but not the actual muscle. Bojadsen et al.¹⁸ supported the absence of other muscle fibers in the back of L5-S1 and indicated that the multifidus represents most of the muscle fibers present on the back of the lumbosacral transition. The very high physiological cross-sectional area of the multifidus relative to other muscles of the lumbar spine, in addition to the muscle's relatively short fibers, indicates that the multifidus muscle is architecturally designed to produce large forces over a narrow range of lengths.¹¹

Muscular instability in the lumbosacral region, whether as a cause of, or as a result of, spinal disorders, has been considered an important problem in spinal surgery and has led to ever-increasing interest in MISS. Paradoxically, classic posterior approaches that disrupt the multifidus and other erector muscles have historically been widely applied, in spite of established evidence that pathological changes of these muscles are associated with various

Fig. 64.1: Cross-sectional MRI image on L4 level showing the interspinalis (IS), multifidus (M), longissimus (LO), iliocostalis (IL), quadratus lumborum (QL), and psoas muscles.

degenerative spinal diseases.^{11,19,20} Taking into consideration the relationship between muscle injury and degenerative spinal disorders, conventional midline posterior approaches may thus be regarded as a cause of iatrogenic muscle damage.

Other risks to the muscles of the lumbosacral spine include denervation and devascularization, which are often unavoidable when wide operative fields are needed and when surgery is performed with a retractor engaged to the lumbosacral spinal muscles. The risk for musculotendinous injury is highest when forceful muscle retraction is performed to achieve wide operative fields for far-lateral discectomy, posterolateral fusion, or manipulation of anterior spinal elements, especially during cases of inadequate midline exposure.^{10,12,21-25}

For the purpose of reducing musculotendinous injury and for preservation of neurovascular supply to back muscles in the posterior approach, anatomical considerations are as important as the details of the surgical technique. For instance, when using a posterior midline macroscopic exposure, accurate dissection of periosteal planes from posterior spinal bony elements, or the so-called subperiosteal dissection, is crucial. Unnecessary dissection of muscles attached to irrelevant parts of bones or joint capsules, excessive use of electrocautery, and excessive and prolonged muscle traction, should all be avoided.¹³ The removal of bony tissue, including spinous, transverse, and articular processes, should not be performed unless necessitated because they comprise the crucial biomechanical framework onto which the back muscles

attach.^{14,24,26} When using a posterior paraspinal exposure, which is usually performed for percutaneous pedicle screw placement or tubular retractor-guided microscopic surgeries, muscle-splitting techniques that involve separation of muscles by index finger dissection can be used to avoid muscle damage.²⁷ One such technique is intramuscular splitting, which uses finger dissection through the multifidus muscle to access the laminae and facet joints (Figs. 64.2A and B).²⁸ Currently, most tubular retractor-guided procedures, including removal of paramedian disc herniation, removal of contralateral intraforaminal disc herniation, unilateral laminotomy for bilateral decompression, and minimally invasive transforaminal lumbar interbody fusion (MIS TLIF), are performed using the intramuscular splitting technique.²⁹⁻³³ Another muscle splitting technique, the intermuscular splitting or cleaving technique, involves finger dissection along the cleavage plane between the multifidus and the longissimus thoracis muscles (Figs. 64.2C and D). Intermuscular splitting between the multifidus and the longissimus thoracis is appropriate for situations requiring percutaneous pedicle screw placement at L1-2 or extraforaminal exposure for removal of far-lateral disc herniation between the L2-5 levels, and is a tried and proven approach since its first description in 1958 by Wiltse as the sacrospinalis splitting method.³⁴⁻³⁸ Dissection between longissimus and iliocostalis lumborum provides for a less invasive access to the pedicle for screw placement in the lumbosacral junction, especially in L3-S2, or for extraforaminal exposure for removal of far-lateral disc herniations at the L4-S1 levels compared with dissecting near or within the multifidus. This is because the iliocostalis is free from attachment to the erector spinae aponeurosis, whereas the multifidus lumborum fans as downward and laterally to attach to the ilium under the longissimus, thereby obstructing the surgical field (Table 64.1).³⁹ Recent evidence strongly suggests that the paraspinal muscle-splitting techniques can reduce back muscle injuries and facilitate access to surgical targets and can provide enough room for changing trajectories by moving the screw guides or the tubular retractors, should the need arise.^{17,24}

SIGNIFICANCE OF NEUROSKELETAL ANATOMY OF THE LUMBOSACRAL SPINE

Understanding the neural structures in correlation with the skeletal structures is crucial for macro- and microsurgical

Figs. 64.2A to D: Illustration showing intramuscular approach through the multifidus (A and B) and intermuscular approach between multifidus and longissimus (C and D).

posterior approaches to the lumbosacral spine. McCulloch and Young⁴⁰ described the neuroskeletal anatomy on the lumbosacral region using a “three-storied house” concept demonstrated here using schematic diagrams (Fig. 64.3). The spinal canal was divided into central canal and lateral zones. The lateral zone includes the lateral recess, intra- and extraforaminal areas. Most acquired central spinal canal stenosis develops in the first story, with some extension of the lesion into contiguous parts of the second story of the same level and the third story of the

adjacent inferior level. Pathologies involving subarticular stenosis, including lateral recess stenosis and central stenosis, could be decompressed bilaterally through a unilateral interlaminar window.⁴⁰

Laminectomy/Facetectomy

Unilateral laminectomy in the lumbar and sacral spine was first performed by Taylor⁶ on a cadaver in 1908. In 1977, Wiltse⁹ first published the surgical procedure of laminectomy on a human patient, referring to the removal

of all bone between the base of the spinous process and approximately 1 cm medial to the facet joints with sparing of the pars interarticularis. If a bilateral laminectomy

is performed, laminae on both sides of the spinal processes, including the spinal process itself, are removed (Fig. 64.4). If laminectomy and facetectomy are performed

Fig. 64.4: Illustrations show laminotomy, bilaminotomy, laminectomy, total laminectomy, medial and lateral facetectomy, and foraminotomy.

concurrently, one lamina is removed from the base of the spinous process and outward to include the ipsilateral inferior articular process, pars, and a portion of the superior articular process of the vertebra below. The amount of bone removed in laminectomy and facetectomy results in a complete unilateral decompression, completely deroofing both the exiting and traversing spinal nerve roots through a single-level procedure.⁹

Theoretically, even if a laminectomy procedure included a partial removal of the pars and facet joints medially, stability should not be seriously compromised.⁹ However, over-removal of the pars and medial facets can increase the risk for instability. Total laminectomy may thus increase or cause vertebral instability unless fusion is performed.⁴¹⁻⁴³ These observations have led to the development and adoption of surgical techniques, which preserve sections of the posterior osteoligamentous arches, such as multiple laminotomy.⁴⁴

Laminotomy/Bilaminotomy

Laminotomy refers to the removal of an inferior portion of one lamina without involving the superior portion of the lamina, inferior articular processes, and, especially, the facet joints. This procedure can more correctly be called bilaminotomy as it is common practice for unilateral adjacent upper and lower laminae to be cut through in order to reveal the spinal canal (Fig. 64.4). Bilaminotomy is

performed for procedures such as spinal decompression and discectomy as it allows for thorough access to the spinal canal without creating excessive biomechanical instability, since the amount of vertebral material removed is minimal.^{9,36} With respect to the preservation of vertebral stability, multiple laminotomy has a great advantage over total laminectomy because the latter involves a much more extensive removal of stabilizing structures.⁴⁴⁻⁴⁶

Conventional Foraminotomy

Central constriction (spinal canal stenosis) is most commonly caused by pathology of the medial part of the inferior articular processes, the laminae, the ligamentum flavum, and sometimes the spinous processes. On the contrary, lateral or nerve-root canal stenosis (foraminal stenosis) is caused by pathology of the superior articular processes and involves the emerging nerve roots, either alone or along with the lateral portions of the thecal sac.⁴⁷⁻⁴⁹

Foraminotomy is a form of decompression surgery suitable for compromised nerve roots, first described by Briggs and Krause in 1945.⁵⁰ Two approaches for conventional foraminotomy exist: the midline approach, used for decompression of traversing nerve roots, and the paraspinous approach, used for decompression of exiting nerve roots (Fig. 64.4). If foraminotomy is performed in addition to a laminectomy or laminotomy, a medial part of the pars

Figs. 64.5A and B: (A) Illustration shows that bilaminotomy on right laminae (stippled area, arrow) and reaching to the opposite side under the interspinous ligament and through undercutting the base of spinous process. (B) Axial view shows nerve root and dural protection while contralateral undercutting.

interarticularis along the traversing nerve root and a portion of the superior articular processes, where they come together forming the facet, are removed. Excessive removal of ipsilateral pars or medial facet may cause fracture of the inferior articular processes or spinal instability.^{51,52}

Facet Joint-Sparing Laminotomy and Foraminotomy

In 1980, Ciric et al.⁵³ proposed lateral recess stenosis as a variant of lumbar spinal stenosis. The lateral recess is the region of the lumbar canal that is bordered laterally by the pedicle, posteriorly by the superior articular facet and ligamentum flavum, and anteriorly by the vertebral body, endplate margin, and disc margin (see Fig. 64.3).⁴⁷ This region corresponds to the supra-axillary region as anatomically defined by Wilmink in 1989.⁵⁴ In cases of unilateral spinal lateral recess stenosis or foraminal stenosis, when employing a midline ipsilateral approach, the retained midline posterior structures can obstruct the view and trajectory of instruments introduced for undercutting the lateral zone. To enhance ipsilateral decompression without violation of facet joint stability, Yong-Hing and Kirkaldy-Willis introduced in 1978 a spinous process osteotomy procedure, and modifications thereof, to increase the surgical exposure of the posterior structures. This permitted facile examination of the lateral recess and foramen, but

it unfortunately caused excessive spinous instability.⁵⁵⁻⁵⁷ Facet joint-sparing foraminal undercutting via the contralateral side can be performed through either midline or paraspinal approaches as a method for minimizing the removal of medial articular bones that is normally performed as a part of the ipsilateral approach. In 1988, Aryanpur and Ducker⁴⁵ demonstrated a multilevel midline unilateral approach with bilateral decompression while preserving contralateral zygapophyseal joints, and Young et al.⁵⁸ described the preliminary report of multilevel subarticular fenestration through a midline approach. The anatomical considerations of the unilateral laminotomy for bilateral decompression through midline approach were described by McCulloch and Young⁴⁰ (Figs. 64.5A and B).

In 1953, Watkins⁵⁹ described a lateral approach to the lumbosacral spine that involved separation of the sacrospinalis and quadratus lumborum muscles to expose the transverse processes. Wiltse modified this approach in 1958 opting instead for a longitudinal separation of the sacrospinalis (erector spinae) muscle group between the multifidus and longissimus muscles to expose the facet joints and transverse processes.^{36-38,45} Wiltse and Spencer³⁸ further refined this paraspinal approach and described this procedure in 1988 as what was first called unilateral laminotomy for bilateral decompression of lumbar spinal stenosis by incorporating a sacrospinalis muscle-splitting technique.¹⁸ The anatomical and surgical considerations

Figs. 64.6A and B: (A) The hatched area demonstrates bilaminotomy and undercutting the adjacent base of the spinous process (surgeon's view). (B) Lines drawing demonstrate the angles of the exposure. The medial angulation of the operating microscope allows the contralateral removal of the ligamentum flavum and leads easy access to the contralateral lateral recesses and foramina.

Source: Original drawings of the unilateral laminotomy for bilateral decompression through a paraspinal approach by Spetzger U, Bertalanffy H, Naujokat C, et al. Unilateral laminotomy for bilateral decompression of lumbar spinal stenosis. Part I: anatomical and surgical considerations. *Acta Neurochir.* 1997a;139:392-6; Spetzger U, Bertalanffy H, Reinges MHT, et al. Unilateral laminotomy for bilateral decompression of lumbar spinal stenosis. Part II: clinical experiences. *Acta Neurochir.* 1997b;139:397-403.

of the unilateral laminotomy for bilateral decompression through a paraspinal approach were finally established by Spetzger et al.^{60,61} in 1997, who described the procedure as an ipsilateral laminotomy and foraminotomy with contralateral undercutting of the lamina, with the possibility of removing the medial side of the hypertrophied superior facet (Figs. 64.6A and B). Tubular retractor-guided to the facet joint-sparing unilateral laminotomy for bilateral decompression in the paraspinal approach was introduced and performed clinically by Khoo and Fessler⁶² and Palmer et al.⁶³ in 2002 (Figs. 64.7A to F). Facet joint-sparing tubular retractor-guided contralateral approach is useful to treat degenerative spinal disease and benign mass lesion such as facet joint cyst as well.^{64,65}

POSTERIOR LUMBAR INSTRUMENTATION PROCEDURES

Since 1911, when Hibbs and Albee first reported the posterior spinal fusion procedure with tibia bone graft for Pott's disease, many modified methods for lumbosacral fusion have been developed.^{59,66,67} The term posterolateral fusion (PLF) was first coined by Campbell⁶⁸ in 1939. Fusion bed preparation was defined by Watkins⁵⁹ as the foremost

important step in PLF, whereby bony decortication is performed in the posterolateral region of the lumbosacral spine, which consists of the articular facets, the pars interarticularis, and the dorsal aspect of the transverse processes.⁵⁹

In 1943, Cloward⁶⁹⁻⁷² was the first to perform the posterior lumbar interbody fusion (PLIF) using a full thickness iliac bone graft for the treatment of ruptured lumbar intervertebral disks. Since then, PLIF has become a widely accepted surgical procedure for degenerative spinal diseases such as central canal stenosis, lateral recess or foraminal stenosis, spondylosis, and spondylolisthesis—virtually all procedures of which require wide posterior decompression with facetectomy. But standalone PLIF with inappropriately sized or malpositioned interbody fusion devices cannot produce enough distraction of the annulus fibrosus and therefore limits restoration of lordosis and may ultimately cause biomechanical instability. In these instances, supplemental stabilization techniques may be required.⁷³⁻⁷⁶

The increased risks for instability led to the parallel development of pedicle screw fixation systems. Posterior lumbar interbody fusion performed with pedicle screw fixation has markedly enhanced fusion success rate.⁷⁷⁻⁸⁰ In 1981, Blume and Rojas⁸¹ described a unilateral

Figs. 64.7A to F: Modern unilateral laminotomy for bilateral decompression through tubular retractors in combination with tilting table method. Note preservation of ligamentum flavum until achieving bilaminectomy and contralateral decompression (A) tubular orientation and anatomical view after initial docking (B and C) and initiation of removing the ligamentum flavum from the midline where the two leaves of the ligamentum flavum meet—an area that is typically identified by the presence of epidural fat (D to F). These techniques minimize the risks of injury to the dura.

Figs. 64.8A and B: (A) Illustration shows posterior lumbar interbody fusion (PLIF), which the stippled area represents bilaminotomy with mostly preserving the facet joint. But ipsilateral root and dura retraction is required for introducing the interbody fusion cages (hatched area). (B) Illustration shows transforaminal lumbar interbody fusion (TLIF) without retraction of root and dura. The stippled area represents medial and lateral facetectomy, which lead necessity of supplementary transpedicular stabilizing instrumentations. (SP: Spinous process; P: Pedicle; TP: Transverse process; IF: Inferior facet; SF: Superior facet; L: Lamina).

approach to PLIF that was introduced in response to the neurological complications associated with the original PLIF technique. Regardless of whether the procedure is performed unilaterally or bilaterally, the PLIF approach requires medial retraction of the thecal sac and traversing

nerve roots for insertion of interbody fusion cages (Fig. 64.8A). This process is associated with risks for neurological damage. To minimize posterior musculotendinous and neural retraction injury and to facilitate the placement of interbody fusion cages, transforaminal

lumbar interbody fusion (TLIF) was introduced by Harms (Fig. 64.8B).⁸²⁻⁸⁵

Vertebrectomy with stabilization have been frequently performed using a two-stage operation with an anterior and a posterior stage. Magerl and Coscia⁸⁶ and Shaw et al.⁸⁷ described a single-stage operation, which involves a posteriorly performed transpedicular corpectomy with posterior stabilization. The introduction of expandable cages made this a more affordable reconstructive surgery, all the while correcting sagittal deformities and improving neurological outcome.⁸⁸

Axial Lumbar Interbody Fusion (AxiaLIF) is an alternative fusion method for vertebral levels L4-S1. Although this surgical method is mostly performed blind and involves unique complications such as rectal injury, fistula, and pelvic hematoma, which require additional surgical planning on the part of spinal surgeons, the overall complication rate of AxiaLIF is relatively low relative to PLIF and TLIF, and is similar to those reported for anterior lumbar interbody fusion approaches.⁸⁹⁻⁹³ However, downsides of this approach include the difficulties with restoration of lordosis, foraminal decompression, and potentially low fusion rates.⁹⁴

MINIMALLY INVASIVE LUMBOSACRAL SURGERY

While macrosurgical exposure surgery has historically had successful neurological outcomes, side effects associated with these surgeries, including iatrogenic back pain, are often unavoidable due to mechanical and ischemic injury of the posterior musculotendinous structures by retraction and/or scar tissue formation—this remains a major concern for modern surgeons and patients.^{1,10,25} To leave the smallest possible “surgical footprint” while still achieving a similar level of surgical and clinical success to that of macrosurgical exposure is the rationale behind MISS. The “four pillars of MISS”—four core principles of orthopedic and neurological surgery that are making MISS possible—consist of microsurgical techniques, minimizing soft tissue injury by the use of less invasive retractor and access technology, navigation, and specialized instruments and implants.⁹⁵⁻⁹⁷ The field of MISS is driven by demand from surgeons and patients, and represents a paradigm shift in the way that spinal surgery is being performed.¹

Development of minimally invasive spinal techniques began with the development of specular and tubular retractors, which resolved the issue of excessive paraspinal tissue damage caused by conventional, macrosur-

gical preparation of visual fields. In 1995, Smith et al.³² introduced the use of tubular retractors which enhanced overall visibility of the surgical field and facilitated the use of microscopic visualization. Initially, tubular retractors were used in laminectomy and discectomy.^{32,98} Later improvements in intratubular visibility allowed for the development of tubular retractor-guided TLIF.²⁹ Tubular retractor-guided minimally invasive TLIF combined with unilateral approach for bilateral decompression and 3D neuronavigation-guided screw placement has since become standard protocol for cases of bilateral root compression with instability.^{31,99}

In addition to technique changes, disadvantages and complications of macrosurgical exposure may spawn new instrumentation, like in the advent of the percutaneous external fixation systems and the internal fixation-based pedicle screw-and-rod system. The use of mechanical systems for placement of rods may mark the beginning of minimally invasive spinal instrumentation.^{100,101} Development of image-guided navigation and associated technologies is also essential for MISS procedures for securing accurate localization of pathology and implant placement on the basis of nondirect visual anatomical references.^{1,102} One current trend is the development of MISS in spinal deformity correction and scoliosis surgery, such as in the use of minimally invasive techniques in multilevel percutaneous pedicle screw and connecting rod placement for extreme lateral interbody fusion or direct lateral interbody fusion.¹⁰³⁻¹⁰⁵

Endoscopic Disc and Decompression Surgery

Initially endoscopy was used for percutaneous biopsy or for inspection of the intervertebral space following open surgery. Subsequently, this procedure had been developed with instrumental improvement into the so-called endoscopic transforaminal technique.¹⁰⁶ The endoscopic posterolateral transforaminal approach targets both exiting and traversing spinal nerves and can be used to directly remove intraforaminal and extraforaminal sequestered discs. For pathologies located in the spinal canal, an interlaminar approach is available.¹⁰⁷ Tsou and Yeung¹⁰⁸ and Yeung and Tsou¹⁰⁹ described the “in-out technique,” which involves an intradiscal removal of a prolapsed disc through the annular defect. Although the endoscopic approach is technically most minimally invasive, the limited mobility of instruments, the impossibility to repair any iatrogenic dura injury, and the stiff learning curve are still problems to overcome.¹¹⁰

Choice of Posterior Approaches to the Lumbosacral Spine

In recent years, spinal operative concepts have evolved rapidly, including access trajectories, operative techniques, static versus dynamic instrumentation, and minimal invasive procedures. Surgical failures can be minimized by correctly choosing the appropriate posterior approach to the lumbosacral spinal lesion. Such decisions are multidisciplinary, and many factors can affect operative results.

The choice and method of trajectory is mainly dependent on the location of spinal pathologies and is influenced by experience and preferences of the surgeon. Furthermore, it is important to understand the feasibility of the surgical technique and to weigh the risks-to-reward ratio in determining what approach to use: conventional versus minimally invasive methods. For example, if a patient presents with mild spondylolisthesis with transient radicular pain, either surgical trajectory—anterior or posterior—can be considered, and the ultimate decision depends on preferences of the surgeon and the patient.

Special considerations are necessary as surgical planning for real cases can be more complex than just selecting a surgical approach and technique. For instance, the skin and underlying soft tissues of recently radiated patients are vulnerable to bleeding and infection, and such patients would require special considerations when it comes to surgical planning.¹¹¹ For overweight patients, careful positioning should be considered when placing them on the operating table for a posterior approach in order to prevent excessive intra-abdominal pressure. Details of the preoperative plan may be influenced by the site of operation, surgical revisions, and the nature of the pathological process itself. In addition, the need to remove bone, or the extent to which skin and fascia need to be excised, can also implicate the choice of approach. Another important consideration is cosmetic effects, such as operative scars, which may influence the patients' choice on surgical trajectory and methods. Cost effectiveness is also of concern; for instance, in Artificial Total Disc Replacements, or in surgical placement of motion-sparing devices through anterior or lateral approaches, clinical outcomes have yet to deem them better than conventional posterior fusion despite higher costs.¹¹² Furthermore, the ability of disc replacements to preserve mobility can often be limited. Complications including heterotopic ossification, spontaneous fusion, and device-related failures are still of

concern for motion-sparing devices; moreover the benefit of these devices in preventing adjacent level degeneration still requires further confirmation.¹¹³⁻¹¹⁶ One must consider the maturity of new treatments utilizing the latest technologies in bioengineered artificial disks, biomechanical instrumentation, and bony fusion material in surgical decision-making, since while these new ideas have yet to undergo the test of time in practice; nevertheless, they may transform the way future surgeons perform posterior lumbosacral surgery.

- » Outcomes

INTRODUCTION

Pathologies involving the sacrum are diverse and rare. Approach and, when necessary, reconstruction of the sacrum is challenging because of its unique anatomical features, biomechanical role, and close apposition to other important structures outside the usual expertise of the spinal surgeon. The complex anatomy of the pelvic region makes resection of sacral tumors a multidisciplinary undertaking. Proficiency in the different surgical techniques of sacral reconstruction is often hard to acquire because of the rarity of their application.

Tumors of the sacrum account for 1–7% of all spinal tumors.¹ Because of their nonspecific initial symptomatology, they tend to be large and locally advanced at the time of diagnosis. They can also be overlooked radiologically, both because of incomplete sacral imaging techniques and because of the intrinsic sacral anatomical properties, which can make lesions in this area hard to define.² The majority are metastatic lesions originating from either hematogenous or solid primary malignancies. The most common primary malignant tumor of the sacrum is a chordoma, while the most common benign tumor is a giant cell tumor. The optimal management of sacral tumors is determined by numerous factors including anatomical characteristics of the tumor, preoperative functional status of the

patient, and, more importantly, intrinsic biology of the tumor.³ While oncologic cure is seldom a goal in metastatic disease, it often is for primary spinal tumors. In fact, surgery plays a key role in the management of most primary tumors. The Enneking classification, originally described for tumors of the appendicular skeleton, remains the fundamental foundation for approaching primary mesenchymal tumors, including those originating from the spine.⁴ For each Enneking stage, a specific resection margin is recommended.⁵ Because most primary tumors originating in the sacrum are chemo- and radio-resistant, en bloc resection with adequate margins is often the only method of achieving local control. Moreover, adhering to the Enneking principles has been correlated with reduced local recurrence rate, improved tumor-free survival, and improved life expectancy, while maintaining acceptable morbidity and health-related quality of life outcomes.^{6–13} Respecting the Enneking principles for aggressive benign and malignant tumors of the sacral region is technically challenging, both from a resection and reconstruction perspective.

This chapter focuses on surgical decision making for reconstruction of the sacrum. Relevant anatomy, biomechanics, reconstruction indications, and strategies are reviewed. A more detailed discussion on sacral tumors will be provided in other chapter of this book.

ANATOMY

A basic tenet of performing any surgical procedure is a good understanding of the relevant anatomy. The human sacrum consists of five separate sacral vertebrae that fuse to form a large triangular-shaped bone. Fusion of the sacrum begins at puberty and is usually complete by 25–33 years of age.¹⁴ The end result reflects the axial load-bearing function of the human sacrum, incorporating the wide sacral ala on each side. The sacrum is concave anteriorly, both in the rostrocaudal and in the mediolateral planes, and convex posteriorly. The sacrum is separated anteriorly from the upper part of the rectum by the sacral plexus, and, at the lower part of the rectum, only a dense fascia intervenes between the two structures.¹⁵ The sacrum articulates superiorly with the L5 vertebral body through the L5-S1 intervertebral disc and the facet joints; inferiorly with the coccyx through ligamentous attachments or bony union; and on each side with the iliac bone through the sacroiliac joints. The sacroiliac joints are synovial structures and end at the S2 level. The lumbosacral junction is located anterior to the sacroiliac joint complex, creating a rotatory force on the sacrum. The force vector is counterbalanced by strong ligaments: the interosseous and posterior sacroiliac ligaments are the strongest of these, resisting forward tilt of the upper end of the sacrum. Other ligaments include the sacrotuberous and sacrospinous ligaments, which resist posterior tilt of the inferior sacrum and coccyx, and the iliolumbar ligaments, which resist forward migration of the L5 vertebral body.¹⁶ Forces are transmitted from the spine to the sacrum and then to the pelvic girdle via the sacroiliac joints.¹⁷ Consequently, spinopelvic stability is not compromised as long as these structures are preserved (see below).

Although a detailed vascular and neural anatomy of the pelvic region is beyond the scope of this chapter, its knowledge is essential before undertaking sacral resection. In fact, at presentation, sacral tumors are often so large that they may distort normal vascular anatomy. The presacral venous plexus may become congested and dilated and be a cause of significant blood loss if overlooked. Preoperative embolization is very useful to better define the patient's specific vascular anatomy and to limit intraoperative blood loss.

CLASSIFICATION OF SACRAL RESECTION

Fourney et al.¹⁸ reported on the Texas MD Anderson Cancer Center experience with sacral neoplasm.¹⁸ On the

basis of their experience on 29 consecutive patients, who underwent en bloc resection of primary sacral tumors, they proposed a novel classification based on the level of nerve root sacrifice as opposed to the level of osteotomy. They divided the type of sacral resections into two groups: those used for midline lesions and those used for eccentric tumors. The midline sacral resection group was further subdivided based on the level of the nerve root sacrifice (Fig. 65.1). Low sacral amputation was defined as sacrifice of S4 nerve roots and below, midsacral amputation as sacrifice of at least one S3 nerve root, and high sacral amputation as sacrifice of at least one S2 nerve root or when only unilateral S1 root sacrifice was necessary. For more locally advanced tumors, when both S1 nerve roots had to be divided a total sacrectomy was performed. When the tumor extended beyond the sacrum to involve the lumbar spine as well, a translumbar amputation or “hemisacrectomy” was performed. The eccentric group included en bloc resection of one sacroiliac joint and hemisacrectomy. This classification of sacral resection has since been used by other centers with lots of experience in dealing with en bloc sacral resections.¹⁹ Another surgical classification for sacral tumors based on anatomical position in the sagittal and cross-sectional plane, as well as anterior extension into the pelvic cavity, has also been proposed.²⁰

SURGICAL APPROACH

Once local and systemic staging is completed, histopathological diagnosis is confirmed, and en bloc resection deemed necessary based on evidence-based principles, multidisciplinary surgical planning takes place. It cannot be overstated that most of these cases require multidisciplinary expertise. The level of the sacrectomy is decided based on the extent of bony involvement and the most proximal roots involved. The expected neurological deficits should then be discussed with the patient to obtain operative consent. The relationship between the anterior extension of the tumor, rectum, and retroperitoneal vessels will also guide the choice of the approach. If the posterior wall of the rectum is involved, a general surgery colleague should be consulted and a diverting colostomy considered. Vascular structures within the pelvis can also be displaced or involved by the tumor, in which case a vascular surgeon can be of a great aid to facilitate the dissection. Finally, a plastic surgeon is often required because of the extensive cavity created by the resection and to assist with flap closure.

Anterior, posterior, combined, and simultaneous approaches have been described in the literature. The goals of the anterior approach are to dissect the anterior portion of the tumor and to ligate the main tumoral vessels.²¹ It allows for careful mobilization of the rectum as well. The anterior approach is also used to harvest the rectus myocutaneous flap that can be used to fill the surgical void in high sacrectomies. The posterior approach is then used to deliver the tumor and to proceed with reconstruction. The combined anterior-posterior approach is mainly used for hemisacrectomy, total sacrectomies, and selected high sacrectomies.^{16,19,21,22} A simultaneous anteroposterior approach is also described,²³ but is often not the preferred approach since it is difficult to expose both anteriorly and posteriorly—as well as when they are done separately—and the approach complicates subsequent reconstruction.¹⁶ The posterior approach alone is appropriate for most high, middle, and low sacral resections.^{16,19} Mc Loughlin et al.²⁴ described a total sacrectomy performed in a single-stage posterior approach. There are three factors that preclude the use of a single-stage posterior approach: tumoral involvement of the rectum, tumoral extension

into the lumbar spine requiring a hemisacrectomy, and involvement of the iliac vessels.²⁵

■ WHEN IS RECONSTRUCTION NECESSARY?

Aside from the already challenging primary oncologic goal of the surgery, restoration of spinopelvic stability is also of paramount importance. A landmark biomechanical study by Guntenberg in the 1970s showed that a partial sacrectomy done at the S1-2 level weakens the pelvic ring by about 30%, and a more extensive submaximal sacrectomy done 1 cm below the sacral promontory, preserving 50% of the sacroiliac joints, weakens it by about 50%.²⁶ On the basis of the physiologic loads transmitted from the sacrum to the pelvic girdle, the authors concluded that weight bearing was safe without reconstruction, as long as at least 50% of the sacroiliac joints were preserved on each side, corresponding to at least the upper half of the S1 vertebra. This indication for stabilization is accepted in the literature.^{18,19} Even if the sacrospinous and sacrotuberous

ligaments are transected with these lower sacral resections, the strong sacroiliac joint-posterior sacroiliac ligament complex suffices to assure stability. The potential for fatigue fracture after high sacral amputation seems to be of limited clinical significance. Bergh et al.⁷ reported that six of 18 patients with high sacral resection (at or above the S1-S2 disc space) developed fatigue fracture in the remaining part of the sacrum.⁷ However, only one patient suffered from disabling pain despite surgical intervention. No patient with sacral amputation below the S1-S2 disc space developed insufficiency fractures. Another biomechanical study, however, concluded that reconstruction should be considered when the sacrectomy is done cephalad to the S1 foramina.²⁷ Hugate et al.²⁷ also showed that the pattern of failure was vertical fractures through the sacrum (most often Dennis zone II), while none of their specimens failed at the sacroiliac joint level.²⁷ Another more recent biomechanical analysis showed that partial transverse sacrectomy involving S1 could result in rotational instability, and resection of greater than half of S1 further leads to compressive instability. The authors then concluded that reconstruction should be considered if the resection is at or above the S1-S2 level.²⁸

When a total sacrectomy is performed, the lumbar spine is entirely disconnected from the pelvic ring and hence surgical reconstruction is indicated despite the added complexity and potential morbidity.^{18,19,29} Reconstruction allows for earlier mobilization and return to activities. Some authors advocate that reconstruction should be avoided because of the risk of infection and hardware failure.^{30,31} Stability is then dependent on the formation of a biologic sling composed of muscle and scar tissue between the pelvis and the lumbar spine. Prolonged immobilization is however required if no reconstruction is attempted. For hemisacrectomy and unilateral sacroiliac joint removal, some recommend upfront stabilization¹⁹ (Fig. 65.2), while some do not routinely perform lumbopelvic reconstruction if the contralateral joint is intact and there is no anterior pelvic deficiency.¹⁸

RECONSTRUCTION STRATEGIES

Multiple lumbopelvic reconstruction techniques have been described.^{16,19,21,29,32-38} Most techniques used are a modification of the Galveston method initially described for neuromuscular scoliosis.³⁹ Gokaslan et al.²⁹ described a modified Galveston L-rod technique for sacral reconstruction after total sacrectomy in two patients harboring a sacral giant-cell tumor. The original technique involves the placement of bilateral L3-L5 pedicle screws. A ver-

Fig. 65.2: Example of a complex reconstruction using a vascularized fibula graft, and instrumentation bridging L3 to ischial tuberosity on the right, and L3 to ileum on the left following a hemipelvectomy and complete resection of the right-sided sacroiliac joint.

Fig. 65.3: Illustration of the initial modified Galveston L-rod technique.

tical rod is then placed on each side from the pedicle screws proximally and then bent laterally in between the two cortices of the ilium distally. Cross-connectors are used to secure the construct. To prevent axial rotation, a transiliac bar is then placed to fix iliac bones to each other. A tibial allograft is used to close the space between the two ilia. A combination of autologous and allogeneic bone graft is

Fig. 65.4: Postoperative X-ray, depicting the updated modified Galveston technique.

Source: With permission from Gallia GL, Haque R, Garonzik I, et al. Spinal pelvic reconstruction after total sacrectomy for en bloc resection of a giant sacral chordoma. Technical note. J Neurosurg Spine. 2005;3(6):501-6.

placed from the transverse processes of L3 to the medio-posterior aspect of the ilium to achieve solid bony union (Fig. 65.3). With follow-up, this construct was found to suffer from some biomechanical limitations. More specifically, this method does not optimally resist axial and rotational forces across the horizontal axis resulting in rod breakage between the L5 pedicle screws and the ilium, and loosening of the iliac portion of the rod, respectively. To overcome these limitations, Gallia et al.³⁶ described an updated version of the modified Galveston technique using poly-axial iliac screws instead of the L-shaped rod. Iliac screws overcome the potential drawback of the difficulty associated with contouring the Galveston rods. A transiliac bar was used and connected to the pedicle screw rods using L-shaped connectors. A rod connecting the iliac screws was then linked to the construct using various cross-connectors (Fig. 65.4).³⁶ Later, a four-rod technique involving bilateral dual iliac screws was described to better address the problem of rod fracture at the lumbo-pelvic junction (Fig. 65.5).³²

Another method of spinopelvic reconstruction, called triangular frame reconstruction, was described by Murakami et al.⁴⁰ After a total sacrectomy has been performed, the spinal column is pulled down (3 cm) and L5

is affixed to the ilium bilaterally with a sacral rod. Another sacral rod extending into the pelvis is then connected to the spinal rod, which is affixed to the pedicle screws of L3-L5 (Fig. 65.6).

Kawahara et al.³⁵ conducted a finite-element analysis of reconstruction methods used after a total sacrectomy. In their analysis, they described a novel reconstruction technique consisting of both posterior and anterior instrumentation. The posterior instrumentation consisted of L3-L5 pedicle screws connected to iliac screws via a rod. Anteriorly, they put two pedicle screws in the inferior endplate of L5 which they connected to a sacral rod, itself connecting to both sides of the pelvis. Using this model, Kawahara et al. concluded that there was a low risk of instrument failure and loosening after total sacrectomy. They compared this technique with the modified Galveston and triangular frame reconstruction techniques, and found that the former was associated with excessive stress at the spinal rod level while the latter led to excessive stress at the iliac bone level.

Another technique using two to three pairs of bicortical iliac screws connected to L3–L5 pedicle screws via a single U-shaped rod has been described.^{19,41} This closed-loop technique is believed to provide improved stability of the lumbopelvic junction in flexion–extension and rotation (Fig. 65.7).

To relieve the stress on the posterior instrumentation and the iliac bone, Dickey et al.⁴² described a new form of anterior reconstruction using structural fibular grafts combined with a pedicle screw-rod instrumentation to create a triangular construct along the anatomic force transmission vectors from the femoral heads to the lumbar spine.

Fig. 65.7: Postoperative X-ray showing the closed-loop U-rod reconstruction technique.

In a case of hemicorporectomy, Gallia et al.³³ described a novel technique of lumbopelvic reconstruction using a distractible cage to reconstruct the anterior column.

A custom-made prosthesis has also successfully been tried to restore spinopelvic stability. On the basis of pre-operative imaging and necessary extent of resection, Wuisman et al.³⁴ reported on the usage of a custom-made sacral prosthesis on one patient suffering from a primary osteosarcoma of the sacrum. One disadvantage of this technique is the inability to make any intraoperative adjustments.

The appropriate method of reconstruction largely depends on the experience of the surgeon and on specific tumor/patient characteristics. Multiple biomechanical studies have, however, been conducted to compare some of these sacral reconstruction strategies.^{35,40,43–47} Kelly et al.⁴⁵ compared the four-rod and the two-rod techniques both with and without cross-links. They found that the four-rod lumbopelvic reconstruction technique provided significantly greater stability in flexion and extension as compared to a conventional cross-linked two-rod technique in a human cadaveric sacrectomy model. The four-rod technique also significantly reduced the motion at the L5-pelvic junction, which may be clinically relevant in achieving solid bony union. The addition of cross-links further improved stability in axial rotation. Yu et al.⁴⁴ reported on biomechanical superiority of dual-iliac screw over the single iliac screw method for cases involving high sacrectomies with unilateral sacroiliac joint resection and for total sacrectomies. The dual-rod dual-iliac screw technique provided the most rigid fixation among the four techniques using posterior fixation only.⁴³ The biomechanical advantage of adding anterior support (either L5 inferior end plate screws/sacral rod, triangular fibular flaps, or a compound method) to the four-rod technique has also been demonstrated,^{35,46,47} at the cost of significant technical difficulties and potential disturbance to the pelvic viscera.

Pelvic incidence is a key determinant of sagittal balance. Pelvic incidence does not change in adulthood, despite traditional lumbosacral surgeries. However, with total sacrectomies and total disarticulation of the sacroiliac joints, pelvic incidence is altered.⁴⁸ Although long-term studies are lacking, change in pelvic incidence may be relevant clinically, and thus should be taken into consideration during lumbopelvic reconstruction.

Another important consideration in total and high partial sacrectomies is the significant surgical cavity created by

the resection. Despite advances in reconstructive microsurgical techniques, the repair of the large void created by tumoral resection remains a challenging undertaking.⁴⁹ This task is further complicated by preoperative radiation therapy and difficult access to adequate recipient vessels in the sacral area. The main techniques used are the vertical rectus abdominis myocutaneous (VRAM) flap, bilateral gluteal advancement flap, gluteal rotation flap, gluteal thigh flap, and free flap reconstruction. The VRAM flap is harvested during the anterior approach and, consequently, cannot be used in posterior approach only. The VRAM flap is thus not the preferred reconstructive method for middle and low partial sacrectomies, typically done with a posterior approach alone. Miles et al.⁵⁰ published their experience of 27 flaps in 25 patients and concluded that in patients with no preoperative radiation therapy and intact gluteal vessels, the use of bilateral gluteal advancement flaps should be an option to consider. When there is a history of radiation to the area or if the gluteal vessels are damaged by the surgical resection, the use of a VRAM flap should be considered. When a previous laparotomy precludes the use of the VRAM flap, then a free flap should be contemplated as a final option. Others have, however, reported that a prior laparotomy has no detrimental effect on the effective or safe use of a transabdominal pedicled VRAM flap.⁵¹ The MD Anderson group reported on their 15-year experience on 50 patients.⁵² In their experience, the resection volume was the main factor determining flap choices: gluteus-based flap being most commonly used for small and medium cavities and VRAM flap as the preferred option for large defects. The overall complication rate was 44%, but the flap choice was not an independent predictor of complications.

Another goal of the soft tissue reconstruction is to avoid parasacral herniation of the abdominal content. This can be accomplished by using a mesh⁵³ or the myocutaneous flap itself.⁵¹

In the case of extensive defects created with posterior approach only, Dasenbrock et al.⁵⁴ published their data on 34 patients with sacral tumors in whom reconstruction was achieved using a human acellular dermal matrix along with gluteus maximus myocutaneous flaps. Of note, gluteal arteries are preserved in a posterior-only approach, assuring a robust blood supply to the gluteus flap. They showed this technique to be a valid option with comparable rate of wound complications to other techniques and low rate of parasacral herniation.⁵⁴

OUTCOMES

Neurological Function

From a neurological perspective, sacral roots often need to be sacrificed to achieve an evidence-based en bloc oncological resection, putting bowel, bladder, and sexual function at risk. Cases of low sacrectomies (distal to S3) usually lead to perineal hypoesthesia and may result in sexual dysfunction.³ Sphincter and motor function are usually preserved, however. Todd et al.⁵⁵ showed that preservation of bowel and bladder continence after major sacral resection is possible in the majority of patients following unilateral sacral root resection or if at least one S3 root is preserved in the case of bilateral sacral resection. A strong association between the number of S3 roots preserved and continence was also reported in another study.⁵⁶ Aside from the expected unilateral sensory-motor loss, most patients with unilateral sacral root resection (S1-S5) will have preserved or partially impaired bowel and bladder functions.^{18,55,57} In cases of total sacrectomies with bilateral S1 root sacrifice, clinically relevant motor deficits may interfere with independent mobility. With intact L5 root function, a significant proportion will, however, be able to ambulate independently after rehabilitation.^{18,19,58}

Postoperative Care and Complications

If successful bony and soft tissue reconstruction has been achieved, patients are mobilized as soon as tolerated postoperatively. They are nursed in specialized airbeds to reduce the risk of pressure sore and wound breakdown. The expected deficits are confirmed postoperatively and rehabilitation initiated as soon as possible. Psychological support should also be offered if needed.

Sacral tumor resections are significant surgeries associated with significant complications. They are also demanding for the surgical team: total sacral resection often lasting >10 hours,⁴¹ and even >30 hours for two-stage procedures.²⁹ Significant blood loss is also to be expected with reported values ranging from 6.5 L to 40 L for single-stage operations and 10.1–80 L for two-stage operations.²⁹ Early postoperative deaths have also been published secondary to cerebral infarction and sepsis.⁵⁹ Other major complications include rectal and other visceral injury, vascular injury, hardware failure, unexpected neurological deficit (which can be secondary to traction injury to the lumbar plexus), dural tear, and wound problems.^{37,59} The proximity of the anus, the risk of incontinence, the possibility of unrecognized rectal injury as well as the

large surgical dead space created, all contribute to significantly high wound complication rates of 25 to 46%.^{25,52,56} In a study of 50 patients who underwent a sacrectomy, Guo et al.⁵⁶ showed that bowel incontinence is associated with delayed wound healing. They concluded that bowel diversion procedures should be considered in select cases when bowel incontinence is expected based on the level of resection. Median length of hospital stay between 6.5 and 91 days is reported. These are significantly influenced by the extent of sacral resection,¹⁸ the use of a flap closure, occurrence of adverse events, and bowel incontinence.⁵⁶

CONCLUSION

Low-grade malignant and aggressive benign sacral tumors are best treated with an en bloc resection with appropriate surgical margins. In the sacral region, it involves performing varying extents of sacral resection. These surgical interventions can be very challenging and should be assessed by a multidisciplinary team in a center with such expertise. Depending on the level of the sacrectomy, spinopelvic instability may occur and reconstruction may become necessary. There is currently no consensus about the best reconstruction technique. Decisions should then be made according to surgeon experience, as well as specific patient preferences and tumor characteristics. Because of the inherent surrounding anatomy of the sacrum and also because the often large size of these tumors at the time of diagnosis, there is a significant risk for potentially serious complications. Expected neurological deficits from such interventions should be discussed at length with patients preoperatively. With careful patient selection and meticulous surgical planning, successful clinical outcomes can be anticipated, although further quality of life studies would certainly add to the current literature.

- En bloc resection with appropriate margins is the treatment of choice for low-grade malignant and aggressive benign sacral tumors.
- Sacral resections are technically challenging procedures and are better dealt with in an experienced center with a multidisciplinary team.
- Meticulous surgical planning and patient selection are key in the successful completion of these resections.
- Lumbopelvic reconstruction is necessary when >50% of the sacroiliac joints are resected and allows for earlier mobilization.
- Multiple spinopelvic reconstruction techniques have been described, the best one being determined by surgeon experience and specific patient-tumor characteristics.

INTRODUCTION

Posterior fixation of the spine to the pelvis is helpful in achieving arthrodesis at the lumbosacral junction, a region with several unique features that pose considerable challenges to fusion. The inclusion of the pelvis in spinal instrumentation constructs significantly reduces deleterious forces on sacral fixation, thus decreasing instrumentation failure, and pseudarthrosis. The techniques discussed in this chapter are particularly useful for long segment constructs ending at the sacrum such as used for pediatric and adult spinal deformity. In spinal deformity surgery, the incorporation of pelvic fixation is often crucial for success.¹ Pelvic fixation is also an integral part of spinal oncologic procedures where the sacrum is involved such as in sacral chordoma, and also is extremely useful in cases where the sacrum is lacking quality bone for screw purchase such as in osteoporosis, infection, trauma, or pseudarthrosis.^{1,2} Although technically demanding, a mastery of these techniques is a powerful addition to a spine surgeon's armamentarium.

The concept of fixation of the spine to the pelvis is not new. Harrington instrumentation is credited as the first spinal instrumentation that could be applied across the lumbosacral junction. The technique employs the use of hooks and rods for fixation, which can place distractive or compressive forces depending on direction of the hooks.³ The major drawback of spanning the lumbosacral junction

with a hook and rod construct is the inherent instability of hooks at the sacrum that carries a risk of dislodgement of 26% and a dismal pseudarthrosis rate that approaches 40%.^{4,5}

Luque improved spinal fixation with the addition of sublaminar wires affixed to the rod construct. An L-shaped bend located at either end of the construct served to limit cranial or caudal migration of the rods that might occur with loosening of the wires. The lumbosacral junction still posed a significant challenge to fusion with this system, and pseudarthrosis rates are reported up to 41%.⁶⁻⁸

The introduction of Cotrell-Dubousset (CD) instrumentation offered more points of fixation including, for the first time, the use of pedicle screws. The original technique consisted of long thoracolumbar rods with multiple interlocking hooks and wires.⁹ With multiple crosslinks, this system had a higher rate of complications due to instrumentation.^{9,10} The CD technique was the first to introduce intermittent monoaxial pedicle screws for further fixation.³ Historically, when pedicle instrumentation is applied at the sacrum alone, high pseudarthrosis rates of up to 33% are reported primarily because of poor flexion control, leading to a pull-out rate as high as 70% in older constructs.^{9,11}

The Galveston technique for fixing the spine to the pelvis was introduced by Allen and Ferguson in the 1980s for the treatment of children with neuromuscular scoliosis

and pelvic obliquity.^{6,7,12,13} The technique involves the contouring of rods that are then inserted into the ilium at the level of the posterior superior iliac spine (PSIS).¹⁴ Rods are impacted between the inner and outer tables of the ilium in the narrow portion of bone above the sciatic notch. Rods are secured to the spine with sublaminar wires as popularized by the Luque technique¹⁵ for adolescent idiopathic scoliosis. It was the fixation to the ilium that was believed to offer the greatest improvement over prior constructs.

With the advent of modern pedicle screw and rod systems for posterior spinal instrumentation, the use of iliac bolts has largely replaced the Galveston technique. Current systems are modular, allowing for easier integration to multisegment fusion constructs that limit morbidity to the patient. Iliac screws can easily be incorporated into a construct with or without the use of an offset connector (depending upon cannulation technique used). This ease of incorporation has translated to greater pull-out strength of up to 300% when compared to Galveston iliac rods.^{3,16} Compared to the poor fusion rates with earlier constructs, lumbosacral fusion rates with iliac bolts have been reported to be as high as 92.5% in recent studies.^{17,18} A recent study of patients with long constructs and iliac fixation for high-grade spondylolisthesis shows a fusion rate of 95% in a series of 81 patients.¹⁹ In this chapter, we will discuss pelvic anatomy, biomechanics, and screw insertion techniques.

■ PELVIC ANATOMY

The sacrum consists of five fused vertebrae and serves as the interconnecting bony bridge for each half of the pelvis via the sacroiliac joint. Typically the male pelvis is larger than the female pelvis and can accommodate instrumentation with increased diameter and length. When planning sacral pedicle screws, it is important to understand that generally, the ventral surface is concave and the dorsal surface is convex.²⁰ The sacral promontory refers to the angulation formed by the ventral surfaces of the adjacent lumbar and sacral vertebral bodies. Due to the interdigitating nature of this joint, there is minimal motion at this junction. Multiple ligaments further restrict motion here, including the dorsal, accessory, ventral, and interosseous ligaments.²¹

Preoperative anteroposterior radiographic imaging should be performed so that adequate and consistent nomenclature and counting be performed. Sacralization of lumbar vertebrae refers to the L5 vertebrae congenitally

fusing to the sacrum, creating a six-bone sacrum. Conversely, lack of fusion of the first sacral vertebrae can lead the patient to have six lumbar vertebrae and said to have a “lumbarized” S1.

When considering proper iliac screw trajectories, knowledge of the anatomy of the pelvis is key. Radiographic measurement studies of the ilium show the maximum canal diameter to be found between the PSIS and the anterior inferior iliac spine (AIIS).²² The maximum mean screw lengths that could be accommodated between these structures are as high as 141 mm and 129 mm in males and females, respectively. Computed tomography imaging studies also illustrate two consistently narrow portions of the ilium: near the anterior surface of the sacroiliac joint, and superior to the greater sciatic notch. This is clinically relevant for screw purchase and when encountering resistance with iliac screw instrumentation.

When including the pelvis in posterior spinal constructs, there are several pelvic anatomic considerations that must be understood. Aside from the more dense sacral alae and bony promontory, the majority of the sacrum is cancellous.³ The most critical structures to consider when instrumenting the sacrum are the vasculature, namely, the internal iliac artery and vein bilaterally, as well as the middle sacral artery and vein. Additionally, a clear understanding of the locations of the key neural structures such as the sacral sympathetic trunk and lumbosacral trunk is paramount. Lastly, the colon should always be thought adjacent to the cortex when considering anterior cortical breaches from posterior sacral fixation or iliac fixation.

■ BIOMECHANICS

McCord et al.²³ offer some insight to the success of iliac fixation in cadaveric biomechanical studies. They define the middle of the osteoligamentous column at the junction of the last lumbar vertebrae and the sacrum as the lumbosacral pivot point, a point of great stress. They show that the further anterior the iliac screws extend past the lumbosacral pivot point, the more stable the construct. Therefore, when crossing the sacroiliac joint, the goal should be to place a screw as anterior as possible.

Iliac fixation has also been shown in biomechanical studies to decrease strain on S1 screws, providing superior biomechanical support when compared to L5-S1 interbody support.^{24,25}

Work by O'Brien^{3,26} has defined three zones of the spine for instrumentation purposes, whereby in the

progression of the zones increased stability of the lumbosacral construct is obtained. Zone one is defined as the S1 vertebral body and the cephalad alae. Zone two is the caudal alae and the coccyx; and zone three includes both ilia.

TYPES OF LUMBOSACRAL FIXATION

The most prevalent construct today at the lumbosacral junction are S1 pedicle screws connected to iliac screws. In a calf model, under axial compression, only the addition of iliac screws to an S1 screw reduced the strain on S1. This was compared to a variety of constructs: S1 and S2 screws (cranial or caudal pointing), or intrasacral rods, as in the Galveston technique.²⁵ The major disadvantage of using iliac fixation is that it has the greatest effect on lowering the range of motion.²⁵

S1 screws, when offered alone as the caudal end of a long segment fusion, have a high rate of nonunion, as high as 44%.^{9,11} This is in part due to the cancellous quality of the bone of S1. The goal of S1 fixation is to increase the fixation strength by achieving bicortical purchase, or even tricortical purchase by targeting the sacral promontory. Recent work has shown that technique plays a chief role in the fusion rate and pull-out strength of S1 fixation.²⁷ The most notable of which is a cadaver study showing that tricortical purchase involving the sacral promontory has a mean pull-out strength twice that of bicortical purchase.²⁷

S2 screws have seen decreased use given studies demonstrating poor pull-out strength, and little increase in overall stability of the construct.²⁸ Alar screws have increased pull-out strength compared to S2 screws as they are more medially directed. Unfortunately, the strength of alar screws is also greatly augmented by being bicortical and medial, which is a risk to critical neurovascular structures, namely, the lumbosacral vein and internal iliac vessels. The safest trajectory is approximately 45° lateral, keeping in mind the risk for unintentional sacroiliac joint penetration.³

ILIAC SCREW TECHNIQUE AND PLACEMENT

Moshirfar et al propose two paths for iliac screws: from the PSIS to the superior acetabulum, or, the more preferred trajectory, from the PSIS to the AIIS. The AIIS is a preferred target because it allows for longer fixation and is further from the sciatic notch. With monopolar cautery, the PSIS

of the ilium is exposed. A Taylor or similar retractor can be quite helpful in achieving adequate retraction of soft tissue. An osteotome can then be used to harvest a small wedge of bone. This allows the bolts to be well recessed into the PSIS so that the patient does not feel them when seated. Fluoroscopy is routinely used to find an ideal and safe trajectory to the ASIS. Cadaver radiographic studies by Schildhauer et al.²² have developed working fluoroscopic trajectories that can assist with ensuring the absence of a cortical breach. A combined obturator oblique-outlet view of 45° cephalad and 45° anterior demonstrates a supra-acetabular view known as the “teardrop sign” that represents a superimposition of the PSIS, AIIS, and iliac cortical rim above the sciatic notch. This is an *en face* view of the screw trajectory that defines the cancellous bone that will be cannulated. Next, a Steffee probe (Medtronic Sofamor Danek, Memphis, TN) is used to cannulate the starting point. This probe is preferred because of the broad, flat tip, which requires much more force than a pointed probe to cause a cortical breach into the pelvic cavity. The ilium is then tapped and a large diameter (8–10 mm) screw is inserted.

Prior work has demonstrated the safe placement of iliac screws using image guidance, limiting the patient and surgeon's exposure to radiation.²⁹ Using a freehand technique, a typical angle is 30° lateral from midline and 25° caudal from the vertical plane.³⁰ The greater trochanter can also be palpated and the trajectory is approximately towards this structure. When using a freehand technique, the surgeon must be aware that the less lateral the angle, the greater the chance that the screw will breach into the pelvic cavity. Ideally the longest screw possible should be placed because, as previously mentioned, as the distance from the lumbosacral pivot point increases, so does the resistance to flexion forces, thereby increasing the effectiveness of this screw as a load-bearing anchor.

Recently, an alternative technique known as the S2 Alar Iliac Screw (S2AI) has been championed by Kebaish and others. In this technique, a starting position approximately 2–4 mm lateral and 4–8 mm caudal to the S1 foramen is created. A pedicle probe is then advanced in a lateral trajectory (approximately 40° to the horizontal plane and 40° caudally) towards the AIIS.¹ The ala of the sacrum and SI joint are crossed prior to entering the ilium. Pelvic fluoroscopic views or image guidance may be necessary to determine the ideal trajectory. A 70–90 mm long screw may be used within this path. The benefits of this technique are less soft tissue dissection, and the pelvic bolt head is

in line with the S1 pedicle screw, obviating the need for offset connectors. Furthermore, a screw placed utilizing the S2AI trajectory has a lower profile than a screw placed through the PSIS. The S2AI entry site was found to be, on average, 15 mm deeper than the PSIS entry site with respect to the skin surface.³¹ This helps reduce the chance of wound breakdown in a most vulnerable location.

EXTENSION OF PRIOR FUSION

There is some debate in the literature as to the proper role of sacropelvic fixation.^{19,32-40} Some argue that constructs spanning L1 to the sacrum require pelvic fixation^{30,32} whereas others argue that the patient will likely fuse without accelerated breakdown of the lumbosacral junction until the fusion cross the thoracolumbar junction.⁴¹ Islam et al.⁴² studied extensions of prior fusions to the pelvis in 41 individuals. Pseudarthrosis was significantly more prevalent in patients weighing over 60 kg ($P = 0.017$). Those admitting to smoking preoperatively had a high rate of nonunion (4 out of 6, 67%).⁴³ The decision to use pelvic fixation is clearly based upon multiple factors including a patient's overall health, bone quality, and the proposed length of a construct. All of these contribute to the success or failure of achieving lumbosacral fusion.

COMPLICATIONS

Iliac bolt placement has demonstrated a benefit of increased fusion rates across the lumbosacral junction. In an uncommon patient population, there are some less common complications that are encountered with the use of iliac bolts. When a solid fusion has been achieved at the lumbosacral junction, the minimal motion that will persist across the sacroiliac junction will place stress and strain on the screw. Some screws will fracture and a halo can be seen on imaging. Patients complaining of persistent pain may prompt removal of the screw. In a series of 395 patients, the incidence of iliac screw removal was 6% ($n = 24$), with the chief complain being postoperative pain.⁴³

Screw prominence, especially in thin patients, is a relatively more common reason for iliac bolt removal. As mentioned above, an osteotomy in the medial wall of the PSIS provides a recess that lessens this prominence, but does not necessarily prevent a complication. Alternatively, an S2AI screw may be placed to further decrease the potential for implant prominence.

CONCLUSION

Posterior fixation of the spine to the pelvis can be helpful in achieving a successful fusion at the lumbosacral junction, a region subject to substantial biomechanical forces. An understanding of the anatomy is the key in the safe insertion of instrumentation.

INTRODUCTION

Although not popularly utilized until the 1990s, pedicle screw fixation in the lumbar spine was first described over 60 years ago. In 1959, Boucher described a technique of augmenting a posterior lumbar fusion with screws directed through the pedicle, creating an “internal splint.” With the addition of careful preparation of the fusion area and well packed bone graft, this strategy allowed for early activity and a reduced incidence of nonunion.¹ Harrington later described a technique using L5 pedicle screws for the reduction and stabilization of L5-S1 spondylolisthesis.² In 1986, Steffee published a method using a segmental plate fixation system that utilized pedicle screws, taking advantage of what he called the “force nucleus”—the point on the vertebral body where the forces from the posterior and anterior elements converge.³

When used as an adjunct to fusion, pedicle screw instrumentation provides several advantages including immediate stabilization and lower pseudarthrosis rates. Some advantages of pedicle screw fixation include fixation across all three columns, a means for deformity correction, early mobilization with potentially decreased rehabilitation time, and minimization of the need for postoperative bracing.⁴ When compared to hook and rod systems, pedicle screws may also allow for a decrease in the number of segments needed for a fusion construct.⁵ In a retrospective review of 39 consecutive patients with adolescent

idiopathic scoliosis undergoing curve correction with lumbar pedicle screws and laminar hooks versus laminar hooks alone, the group receiving pedicle screws exhibited significantly better curve correction.⁶

Pedicle screw instrumentation has been associated with a number of disadvantages as well. Increased infection rate, a steep learning curve, neurologic injury, increased operative time and blood loss, loss of fixation, screw breakage, greater cost, and higher reoperation rates have all been cited as potential disadvantages.⁴ The results of instrumented (using pedicle screws) and non-instrumented fusions have been compared as well, with the consensus being that pedicle screws can decrease the rate of pseudarthrosis but do not necessarily improve overall patient outcomes.⁷⁻¹¹ Given these findings, the use of pedicle screw instrumentation should be considered carefully and employed only if the benefits outweigh the risks.

ANATOMY

The anatomy of the lumbar pedicle, as alluded to by Steffee, makes it particularly useful for obtaining the purchase necessary to provide adequate internal fixation. The pedicle is the strongest portion of the vertebra so it is ideal for the application of forces with segmental fixation.¹² Although the lumbar pedicle is well suited for this purpose, it is also in close proximity to the dural sac and nerve roots. Ebraheim et al. defined the anatomy of the lumbar pedicle

with regard to the thecal sac medially and nerve roots both superiorly and inferiorly. They found the average distance between these structures to be 1.5 mm, 5.3 mm, and 1.5 mm respectively.¹³ In a similar study by Soyuncu et al., the authors calculated the interpedicular distance (i.e. distance from the pedicle to the superior nerve root) and distance from the pedicle to the dural sac to be significantly greater at the L5 level.¹⁴

Regarding the average diameter and direction of the lumbar pedicle, it has been shown that there may be significant variation among individuals, without any clear patterns between races and gender.¹⁵ The lumbar pedicle runs ventrally starting at a point at the midline of the transverse process and the lateral boarder of the pars interarticularis. Going from cephalad to caudad, the lumbar pedicle demonstrates increasing medial angulation with an average angle of 12° at L1, 30° at L5, and up to 39° at S1. The sagittal angle extends in a slightly cephalad direction at L1 and is more caudal at L5. Pedicle diameter varies throughout the lumbar spine with L5 typically being the largest with an average diameter of 18 mm and L1 the smallest at 9 mm.^{16,17}

It is important to recognize morphologic variations in the lumbar spine as well, specifically of the L5 and S1 segments. Transitional anomalies at this level include sacralization of the L5 vertebra or lumbarization of the S1 vertebra. When these variations exist, the anatomy and trajectory of the pedicles can change as well; specifically, sacralization results in reduced dimensions for pedicle height, and sagittal and transverse angles, while lumbarization is associated with a reduced length between the facet joint and the sacral promontory. Careful preoperative planning is therefore necessary to address these changes when they are present.¹⁸

PEDICLE SCREW DESIGN AND BIOMECHANICS

A pedicle screw consists of a head, neck, and body. It has inner and outer diameters with the difference between the two measurements representing the thread depth. The pitch of the screw is the distance between the crests of two adjacent threads (Fig. 67.1). The pullout strength of a pedicle screw is related to these physical dimensions. When a pedicle screw pulls out, the bone between the threads becomes fractured. Thus, the pullout strength of a pedicle screw is related to the outer diameter, distance between the threads, and the quality of bone between the threads with the outer diameter of the screw being the most

Fig. 67.1: Diagram of a typical pedicle screw.

important characteristic. Pullout strength is also affected by the trajectory of the pedicle screws in that 30° of convergence in the coronal plane is associated with a 28.6% increase in the forces required to bring about failure.¹⁹

The lumbar pedicle itself approximates a cone from dorsal to ventral so screws designed to mimic this shape have been shown to have higher pullout strength. A conical screw has major and minor diameters that refer to the diameter of the screw at the hub and at the screw tip, respectively. In a biomechanical analysis of different types of pedicle screws in calf lumbar vertebra, Inceoglu et al. found that conical screws showed greater stiffness, insertional torque, and pullout strength when compared to traditional cylindrical screws.²⁰

Insertional torque is another property of the pedicle screw and bony interface that is thought to influence pull-out strength although its role is somewhat controversial. In a study by Zdeblick et al. employing 30 human cadaver lumbar vertebra, insertional torque was determined to be directly related to pullout strength with no correlation between pullout strength and bone mineral density.²¹ Okuyama et al. measured the insertional torque of screws that were placed in 62 consecutive patients undergoing posterior lumbar interbody fusion and there was a direct correlation with bone mineral density, but not with screw pullout and failure.²² In the biomechanical analysis cited previously, Inceoglu et al. also reported that changes in screw design affected insertional torque but not pullout

strength.²⁰ Overall, many surgeons prefer a pedicle screw design with high insertional torque due to their superior tactile feedback.¹⁹ However, whether or not this translates into increased pullout strength has yet to be fully determined.

SURGICAL TECHNIQUE

After exposing the posterior elements, the starting point for a pedicle screw is generally located at the junction of a vertical line running along the lateral aspect of the facet joint (or alternatively the lateral border of the pars interarticularis) and a line drawn horizontally through the middle of the transverse process (Fig. 67.2A). Fluoroscopy or surgical navigation systems may also be employed to verify trajectory. In a meta-analysis assessing a total of 7,533 pedicle screws, computed tomography (CT)-based in vivo navigation systems gave rise to 90.76% accuracy versus 85.48% for conventional fluoroscopy.²³ In another cadaveric study, the combination of CT navigation and verification using a ball-tipped probe was 98% sensitive and 80% specific in the lumbosacral spine.²⁴ Nevertheless, the benefits of this

technology must be weighed against increases in cost and radiation exposure to the patient and surgeon alike.

Once the entry site has been identified, a cortical window is created using a high-speed bur or an awl (Fig. 67.2B). A pedicle probe is then used to develop an appropriate path for the screw that should be approximately parallel to the superior endplate of the vertebral body in the sagittal plane (Fig. 67.2C); the coronal trajectory will vary depending upon the level of the spine. At L1, the probe should be aimed approximately 10–15° obliquely across the pedicle and this angulation will increase 5° at each caudal level so that at S1 the trajectory should be 25° medial and 10° inferior. The pedicle finder is typically inserted to a depth of 35–40 mm and care should be taken not to penetrate the cortices of the pedicle or the ventral vertebral body. The pedicle probe is removed and a ball-tipped probe is passed along the tract to ensure there are no cortical violations. In dense bone, a tap may be used to optimize screw purchase although this may not be necessary in patients with osteoporosis (Fig. 67.2D).

Prior to insertion of the screw, the pedicle is palpated with a ball tip probe once again. Sedory et al. tested this

Figs. 67.2A to E: Lumbar pedicle screw insertion technique. (A) The starting site of a typical lumbar pedicle screw is at the intersection of a line drawn through the lateral border of the facet and a line drawn horizontally through the transverse process. (B) A high speed bur is used to break the cortex. (C) A pedicle finder is inserted to create a path for the screw and the screw is appropriately measured. (D) A tap is inserted to optimize screw purchase. (E) The appropriate size screw is inserted.

technique in cadavers and showed that it was 81% accurate for confirming the integrity of intact pedicles but was much less reliable for determining the exact location of a breach. The authors concluded that sounding the pedicle with a ball-tipped probe alone may be insufficient for detecting a cortical defect and should therefore be used with caution.²⁵

After the continuity of the tract has been confirmed, an appropriately sized screw is then selected and inserted across the pedicle into the vertebral body (Fig. 67.2E). In general, the largest diameter screw that is able to be safely accommodated by the pedicle should be used to maximize purchase. An *in vitro* study by Brantley et al. demonstrated increased fixation stiffness if the screw fills the pedicle by 70% or more, or penetrates the vertebral body by >80%.²⁶ As discussed previously, pedicle length and diameter may vary depending upon the vertebral level and individual anatomy so it is obviously important to review the preoperative imaging studies and pay careful attention to tactile cues while placing screws.

COMPLICATIONS

Lumbar pedicle screw fixation can be technically challenging that may entail a steep learning curve. While the overall complication rate including all potential hazards is not insignificant, most of these adverse events are not considered to be severe. Jutte and Castelein retrospectively evaluated 105 consecutive lumbar or lumbosacral fusion cases supplemented with pedicle screws and noted a complication rate of 54%.²⁷ In the series of Whitecloud et al. consisting of 40 patients who underwent spinal fusion using a variable plating system, the incidence of all adverse events was found to be 45% that increased to 63% with reoperations.²⁸ In their review of 617 fusions, Esses et al. reported intraoperative and overall complication rates of 9.6% and 27%, respectively.²⁹

Fortunately, neurologic injury arising as a result of pedicle screw placement is a rare occurrence. Davne and Myers observed neurologic complications in only 1.1% of 486 instrumented lumbar fusion cases with a 0.4% incidence of nerve injury due to screws breaching the pedicle.³⁰ In a meta-analysis of 35,630 pedicle screws, Gautschi et al. reported the rates of dural punctures and root irritation to be <0.20%.³¹

Even though the risk of neurologic injury is relatively low, intraoperative neurophysiologic monitoring during lumbar spinal surgery has become more prevalent,

especially with the emergence of minimally invasive techniques.³² In an animal model, screws associated with a cortical defect exhibited significantly lower evoked potentials compared to those within intact pedicles.³³ In a prospective study of 90 lumbar fusion cases employing transpedicular fixation, Glassman et al. showed that the utilization of intraoperative electromyographic stimulation to assess the accuracy of screw placement was 98% effective as verified by postoperative CT scans.³⁴ Nevertheless, routine intraoperative neurophysiologic monitoring is not universally accepted as the “standard of care” for these procedures because detractors insist that there is still no definitive evidence indicating that these adjunctive modalities actually improve patient outcomes.³²

With instrumentation becoming more common in the lumbar spine, the incidence of surgical site infections has increased as well. In a case series involving thoracolumbar fractures stabilized with pedicle screw constructs, the overall infection rate was 10% but individuals with neurologic injuries appeared to be at greatest risk.³⁵ In contrast, the prevalence of infection appears to be lower with elective surgeries where the published rates have ranged from 0.8% to 4.7%.^{27,29,36,37}

In the presence of a documented infection requiring formal irrigation and debridement, it is generally recommended that the instrumentation be left in place unless it has loosened or failed in order to maintain spinal stability and avoid any loss of correction or progressive deformity indicative of a nonunion.³⁸⁻⁴⁰ However, in many instances these individuals may require multiple surgical procedures to address their infections. Ho et al. retrospectively reviewed 53 pediatric patients who developed postoperative infections after posterior spinal fusion procedures for scoliosis and found that 47% of these cases in which the implants were retained hardware necessitated serial debridements.⁴¹ In a prospective study of 13 patients with deep wound infections whose pedicle screws were not removed during a subsequent reoperation, there were no significant differences in outcomes compared to a control group with no history of infection at an average follow-up of 22 months.⁴² Even though there is some evidence suggesting that lumbar instrumentation may not need to be removed in the setting of a postoperative infection, the surgeon must still weigh the risk and benefits of retaining the hardware in these situations. It has been shown that titanium instrumentation is less susceptible to biofilm adherence that is known to play a role in long-term colonization;^{43,44} this inherent resistance of titanium is one

reason why it has become the biomaterial of choice for spinal instrumentation.

Fixation failure is another well-recognized complication of pedicle screws. In the previously cited review of Gautschi et al. the rate of screw pullout ranged between 2% and 7.5%.³¹ As discussed in the preceding section, the biomechanical profile of these implanted is affected by both bone quality and screw design but correct screw placement may also decrease the stresses applied to the pedicle. Youssef et al. showed that screws directed more cephalad as opposed to caudal or parallel to the superior endplate resulted in a greater mean bending moment across the pedicle.⁴⁵ A number of different salvage methods have been described such as cement augmentation, reintroduction of a larger diameter pedicle screw, adding supplemental instrumentation (i.e. laminar hooks), or extending the fusion that significantly decreases segmental motion across any levels of suboptimal fixation.²⁰ When revising a failed construct, Gautschi et al. stated that restoring sagittal balance is “mandatory to prevent new screw pullout.”³¹

Other complications associated with the use of pedicle screws in the lumbar spine include hardware prominence that may even necessitate implant removal, particularly in thin individuals. Finally, transpedicular fixation may contribute to the development of adjacent level degeneration if the screws impinge on the facet joint of a vertebra that is not intended to be incorporated into the arthrodesis.¹²

MINIMALLY INVASIVE TECHNIQUES OF LUMBAR PEDICLE SCREW INSERTION

Less invasive techniques of lumbar fusion have gained in popularity in recent years. The technique of percutaneous pedicle screw insertion in the lumbar spine was first described by Magerl in 1984 with the pedicle screws connected to an external fixation device.⁴⁶ Lowery and Kulkarni described a technique for posterior lumbar internal fixation using percutaneous technique with the insertion of rods and connectors to supplement anterior lumbar interbody fusion. In a case series of 86 patients undergoing lumbar interbody fusion with this technique the authors reported a 96% successful fusion rate.⁴⁷

The goals of minimally invasive techniques are to decrease postoperative pain and shorten recovery time by eliminating soft tissue disruption caused by excessive dissection and prolonged skin and muscle retraction. Percutaneous techniques potentially reduce trauma to the two

main posterior spinal muscle groups, which are the deep paramedian transversospinalis muscle group and the erector spinae muscles. These muscles run along the thoracolumbar spine and contribute to dynamic stability of the spine. Preservation of these muscles has been shown to increase lumbar extension strength by >50%.⁴⁸ It has also been hypothesized that the maintenance of physiologic motion by preserving these paraspinal muscle groups can prevent adjacent segment degeneration, although to date this has not been shown clinically.⁴⁹

As a whole, minimally invasive techniques in the lumbar spine have been shown to be cost effective. In a review of prospectively collected registry data, Lucio et al. looked at 101 patients treated with open lumbar interbody fusion compared to 109 patients treated with minimally invasive spine surgery for stenosis with instability. Mean total hospital costs in the open group were \$27,055.53 and \$24,320.16 for the minimally invasive group. There were also more complications and adverse events (including deep vein thrombosis, emergency room admissions, hospital readmissions, reoperations, etc.) in the open group compared to the minimally invasive group.⁵⁰

Percutaneous pedicle screws are typically cannulated and placed over a guide wire. Intraoperative fluoroscopic guidance is utilized. Incisions are made lateral to the midline to allow for medial trajectory of the screw. A Jamshidi needle is used to locate the starting site of the pedicle, and is subsequently advanced through the pedicle and into the vertebral body (Fig. 67.3A). After removal of the trocar, a guide wire is passed through the needle and advanced into the vertebral body (Fig. 67.3B). The Jamshidi needle is then removed and a series of dilators is passed over the guide wire to create a working portal through the paraspinal muscles (Fig. 67.3C). A tap is then inserted over the guide wire, which can be calibrated to the dilator in order to measure screw length (Fig. 67.3D). A pedicle screw is then inserted over the guide wire (Fig. 67.3E).⁵¹

Minimally invasive systems are available for posterolateral fusion and transforaminal lumbar interbody fusions (TLIFs) as well. Using tubular retractors or a paraspinal muscle splitting approach, the transverse process and the facet joint can be exposed for bone graft and pedicle screw insertion with minimal muscle stripping. Once the surgical field is established, the remainder of the procedure may be performed under loupe magnification or with an operating microscope. Connecting rods can also be inserted through small stab incisions.^{49,52}

Figs. 67.3A to E: Percutaneous lumbar pedicle screw insertion technique. (A) A Jamshidi needle is used to locate the lumbar pedicle and is inserted into the vertebral body. (B) A guidewire is inserted through the needle. (C) A series of dilators is passed over the guidewire to create a working portal. (D) A tap is inserted over the guidewire to create a path for the pedicle screw. (E) A pedicle screw is inserted over the guidewire.

Mid-term clinical outcomes of less invasive lumbar fusion using percutaneous pedicle screws have been promising. Foley and Gupta performed a clinical trial of 12 patients undergoing either a one or two level fusion using a percutaneous tubular retractor system. At an average follow-up of 13.8 months, the authors reported excellent results in six patients, good results in five, and poor results in one.⁵³ In a case series of 29 consecutive patients undergoing posterolateral fusion with percutaneous techniques for symptomatic spondylolisthesis, Harris et al. reported outcomes that were comparable to prior studies using open techniques at 12 months follow-up.⁵⁴ In a retrospective review of 80 patients undergoing single level decompression and posterolateral fusion, 37 of which were minimally invasive and 43 of which were open, Kotani et al. showed that, at 2 years follow-up, the minimally invasive approach reduced low back pain and improved functional activities of daily living compared to the open technique.⁵⁵

Pedicle breach and neurologic injury with the percutaneous technique has been well studied and rates have

shown to be comparable with the open technique. Smith et al., in a study of 151 patients undergoing TLIF with placement of 601 total percutaneous pedicle screws under fluoroscopic guidance, reported a pedicle breach rate of 6.8% with only 2 screws causing neurologic symptoms.⁵⁶ In a retrospective review of 424 percutaneously inserted pedicle screws in the thoracolumbar spine in 88 patients, Raley et al. reported a 9.7% rate of misplaced pedicle screws with only one misplaced screw causing neurological symptoms.⁵⁷

Violation of the facet capsule during pedicle screw insertion can result in a significant amount of postoperative back pain. Although the rates of pedicle breach with the percutaneous technique are comparable to the open technique, rates of facet violation have been shown to be higher. In a cadaveric study by Patel et al. involving the insertion of 48 percutaneous pedicle screws by experienced surgeons under fluoroscopic guidance, they reported a 58% rate of facet violation. The authors went on to classify the violation type, which could be useful in future studies to determine the clinical significance of these facet violations.⁵⁸

The minimally invasive technique for pedicle screw insertion in the lumbar spine is a promising approach to treatment of both traumatic and degenerative conditions of the lumbar spine. The benefits of this technique, which are decreased blood loss, decreased postoperative pain, and earlier functional recovery post operatively, must be weighed against the limitations of this technique that are increased operating times, greater radiation exposure to the patient and operating room staff and, as highlighted above, the potential for facet joint violations. These techniques are also associated with a steep learning curve that the surgeon must overcome in order for patients to reap the benefits of the minimally invasive approach.

KEY CONCEPTS

- Lumbar pedicle screws have become the standard as a means for providing internal fixation in the lumbar spine.
- It is important to understand the anatomy of individual pedicles within the lumbar spine as the pedicles change in diameter, take on a more caudal and medial trajectory as one goes cephalad to caudad.
- Intraoperative navigation techniques including two-dimensional fluoroscopy and CT have been shown to increase the accuracy of pedicle screw insertion while minimizing potential of pedicle breach.

- Complications resulting from lumbar pedicle insertion, which include neurological injury, infection, and pedicle breach or fracture, occur at relatively low rates.
- Percutaneous techniques for the insertion of lumbar pedicle screws have the potential to substantially decrease postoperative pain, allow for earlier return to function, decrease hospital stay, and ultimately reduce the overall surgical cost; however, these benefits must be weighed against the limitations of a steep learning curve, longer operative time, and a reported increased rate of facet violations.

INTRODUCTION

Posterior lumbar fixation has been used in conjunction with bone grafting techniques to achieve bony fusion.¹ The probability of achieving a bony fusion is improved with rigid fixation. Pedicle screw (PS) fixation in the lumbar spine remains the good standard for rigid fixation.^{2,3} Its long-standing use also underscores its biomechanical strength and efficacy in providing a rigid construct for an arthrodesis. However, utilization of PS fixation often necessitates a wide posterior exposure with soft tissue dissection and disruption of a portion of the facet joint. In addition, the ease of insertion and safety has been debated for several years.⁴⁻⁶ Lonstein et al. reported a 2.4% incidence of misplaced PSs and a 23–24% incidence of late-onset discomfort related to screw placement or a pseudarthrosis. Overall, the safety and accuracy of PS fixation has improved in the thoracic and lumbar spine using a free-hand technique, advanced imaging, or even navigation in the revision setting.⁷⁻¹⁰ Of note, misplacement of PSs is more common in the thoracic spine, but rarely leads to neurologic or vascular compromise.¹¹

To avoid the risks associated with PS fixation in the lumbar spine, alternative means of posterior lumbar fixation have been developed. Advocates for these fixation options cite less soft tissue dissection, minimized disruption to the adjacent facet joint capsule, decreased neurologic risk, decreased implant cost, and a minimally

invasive approach, with comparable results compared to PS systems.¹² Less rigid facet screw fixation systems also allow for implant-host load sharing and increased micro-motion, which may promote a biological fusion.¹³ However, excessive motion may also lead to a pseudarthrosis and early hardware failure. The fixation options discussed in this chapter include ipsilateral transfacet fixation, translaminar facet fixation, and cortical screw (CS) fixation. Landmark anatomic, biomechanical, and clinical outcome studies describing the technical placement and efficacy of these fixation options are reviewed.

TRANSFACET SCREW FIXATION

Ipsilateral lumbar transfacet screw (TFS) fixation was first described by King in 1948.¹⁴ Later, this was method of fixation modified by Boucher in 1959 to help achieve fusion in the lumbosacral spine using screws placed across the facet joints.^{15,16} The original descriptions of TFS placement were made through the ipsilateral lamina across the facet joint (Fig. 68.1B). Techniques were later developed to place facet fixation from the contralateral lamina (Fig. 68.1A).¹⁷ The terminology regarding these differing techniques at times has been not clearly defined.

In an anatomic and radiographic analysis, Su et al. described the anatomy of the superior and inferior articulating processes for the L2 to S1 levels.¹⁸ These anatomical relationships were confirmed by a magnetic resonance

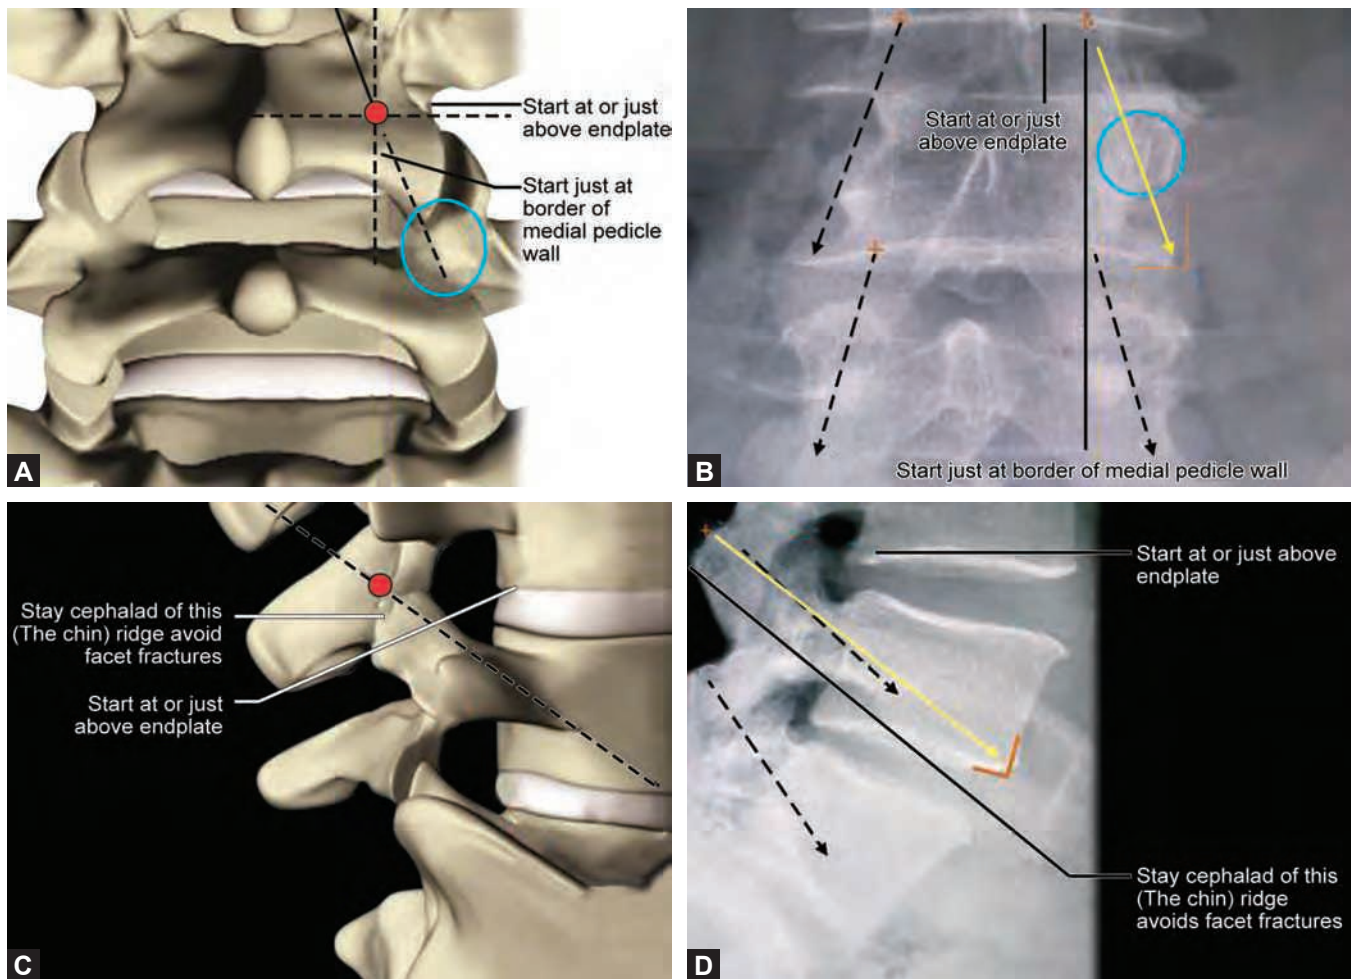

Figs. 68.1A and B: (A) Illustration of transfacet screw fixation from the contralateral lamina. (B) Illustration of transfacet screw fixation from the ipsilateral lamina.

imaging (MRI) study in 100 normal children.¹⁹ By placing pins in cadaveric specimens, the authors were able to identify the screw length, screw trajectory in the sagittal (ϕ , Fig. 68.2A), and axial planes (β_2 , Fig. 68.2B), as well as the ideal starting point for the L3-S1 levels (Fig. 68.2C). Due to the vertical orientation of the facet joint at L2-L3, this level was not amenable to an ipsilateral TFS. In the sagittal plane, the screw should be directed towards the inferior half of the inferior segment with a caudal angulation (ϕ) of 26° at L3-L4, 29° at L4-L5, and 31° at L5-S1. This angle is measured relative to intervertebral disc. For the axial plane, the screw should be laterally angulated 14.6° at L3-L4, 15.3° at L4-L5, and 17.6° at L5-S1. The starting point in the cephalad caudal plane lies at the inferior end plate, while in the medial lateral plane is within 1 mm of the medial wall of the pedicle.¹⁸ Overall, the direction of the screw has been generalized to be “down and outward.”¹³

Chin et al.²⁰ recently described a transfacet PS at L4-L5 in which the traditional TFS technique is modified such that the screw traverses both the facet joint and the pedicle ending in the vertebral body of the caudal level. Anatomically, the start point is once again at the medial pedicle wall and the inferior end plate of the proximal vertebral body (Figs. 68.3A to D). After a midline incision and exposure of the L4 lamina, A Jamshidi needle is placed

Figs. 68.2A to C: For transfacet screw fixation, these figures show the caudal angulation relative to the intervertebral disc (A), the lateral angulation relative to the spinous process (B), and the start point (C).

Figs. 68.3A to D: These figures show once again the start point for the TFS technique on an illustrated model and radiographic view in the coronal (A and B) plane and sagittal (C and D) plane.

on the L4 lamina just medial to the inferior facet. After confirming anteroposterior (AP) and lateral trajectory with via fluoroscopy, a mallet was used to drive the needle in a caudal and lateral direction. Correct position is confirmed with imaging after which a 5.5×50 mm cannulated screw placed.²⁰

ADJUNCTIVE TRANSFACET FIXATION

Published non-union rates for anterior lumbar interbody fusion (ALIF) procedures in the lumbar spine may be as high as 24%.²¹⁻²³ In part, these results have been the impetus for augmenting ALIF instrumentation with additional posterior fixation to improve rigidity. While PS systems in the lumbar spine remain the gold standard for posterior spinal fusions largely due to their biomechanical strength, over the last few years there have been numerous

biomechanical studies reporting on the efficacy of ipsilateral TFS as an augment to ALIF or lateral interbody fusion techniques.²⁴⁻²⁶

Volkman et al. was one of the first to show that posterior TFS fixation improved construct stiffness in compression and extension after ALIF in a cadaveric model.¹² In another biomechanical study, Mahar et al. compared a percutaneous 4.5 mm TFS system with 5.5 mm PS when used with an anterior cage with a compression load cells. The TFS allowed for screw length measurements and compression across the facet joints. The trajectory of screws was also modified slightly from Boucher to obtain purchase with the pedicles of the inferior vertebral body.¹⁵ The author reported no differences between groups in stiffness or load fluctuation with flexion, extension, lateral bending, and torsion of the L4-L5 cadaver specimens.

Ferrara et al.¹³ assessed the relative efficacy of TFS (4.5 mm × 40 mm, lag screws) and PS systems (6.5 mm × 45 mm, fully threaded screw with 6.5 mm titanium rod) with short- and long-term repetitive cycling. In short-term testing, both screw systems showed equivalent stiffness and range of motion (ROM) when used in conjunction with an anterior device. Long-term testing (180,000 cycles, 6 weeks) showed 1°–3° of residual motion that remained constant for the testing period and equivalent between groups. In a cadaver study of L4–L5 vertebrae, Agarwala et al. showed that TFS had similar rigidity to bilateral PS in flexion-extension. In axial rotation and lateral bending, TFS offered less rigidity than PS systems when used in isolation. The differences, however, were minimal when posterior fixation was used as an adjunct to anterior column support.²⁷ Kretzer et al. did a similar cadaveric study for lateral interbody arthrodesis and found no differences in ROM at L2–L3 and L4–L5 for isolated lateral cage, lateral cage + TFS, and lateral cage + bilateral PS.²⁶ Overall, these studies suggest that transfacet fixation is comparable to PS fixation when used in conjunction with an anterior or lateral interbody cage. Pedicle screw systems remain biomechanically superior, however, when used in isolation.

In a clinical study, Voyadzis and Anaizi described the technique of TFS fixation in 10 patients also undergoing an extreme lateral interbody fusion. The authors report safe and effective percutaneous transfacet fixation in the lateral decubitus position at L3–L4 and at L4–L5, with utilization of a midline incision centered over the spinous process. Using image guidance for localization, the starting point for the screw was confirmed with a Jamshidi needle at the inferior end plate and midpoint of the pedicle. As described above, Kirschner wires were driven through the facet joint with a 30° caudal and 15° trajectory after which a cannulated screw is placed. The author noted that TFS—as opposed to PS fixation—reduced operative time and surgical morbidity in select cases. Mean operative time was under 3 hours, blood loss <30 mL, with mean hospital stay under 48 hours.²⁸

■ TRANSLAMINAR SCREW FIXATION

Placement of translaminar screw (TLS) fixation requires that 4.5-mm CSs are inserted from each side of the spinous process of the upper vertebra. These screws are passed through the lamina across the facet joints and end at the transverse process of the contralateral lower vertebra (Aepli et al. 2009).²⁹ Early clinical results and a technique for TLS was described by Jacobs et al.³⁰ in 1989 using a 4.5-mm

screw of approximately 50 mm in length. Results from 43 patients demonstrated a 91% fusion rate with 93% clinical improvement in axial back pain at 6 months.³¹ Aepli et al. reported 10-year follow-up data from 643 patients treated with TLS fixation for a variety of diagnoses. Overall, 74% of patients reported a good outcome with 92% of patients reporting a good outcome if the preoperative disc height was <80% of normal. The authors suggested that preoperative disc collapse resulted in less segmental motion and was protective against a pseudarthrosis. Interestingly, there was also a trend towards improved outcomes in patients with degenerative spondylolisthesis rather than degenerative spondylarthrosis.²⁹

■ ADJUNCTIVE TRANSLAMINAR FIXATION

A majority of biomechanical studies have focused on the use of TLS fixation in conjunction with anterior cages. Phillips et al. demonstrated that ALIF cages at L5–S1 have the greatest angular motion and least compressive preload under extension. When ALIF cages were supplemented with TLS, the angular motion was significantly reduced in extension compared with cages alone or the intact spine.³¹ Harris et al. showed that a one-level transforaminal lumbar interbody fusion (TLIF) with a cage did not increase overall spine flexibility, but did result in increased axial rotation at L4–L5. When used as an augment, bilateral PS increased stiffness the most followed by unilateral PS, then unilateral TLS.³² In contrast, Razi et al. found no differences in ROM when either TFS or PS was used in conjunction with a femoral ring allograft in cadaveric study.³³

For two-level ALIF, Eskander et al. reported that either PS or TLS decreased in flexion and, to a smaller degree rotation when compared to an intact spine. However, there was no difference between instrumented and non-instrumented spines in extension. Overall, there was a tendency towards increased stiffness with pedicle versus TLSs, but the difference was not statistically significant.³⁴

In contrast, Zhan and Tian showed two-level posterior augmentation of ALIF cages improved stiffness compared to the intact spine or anterior instrumentation. The type of posterior fixation—PS versus TLS—did not affect outcome.²⁴ Similarly, Hou et al. found anterior cages used for two-level fusions augmented with either TLS or PS had increased stiffness as compared to an intact spine or ALIF cages alone. However, there was no difference between in stiffness, ROM, or adjacent disc pressure for TLS versus PS.²⁵

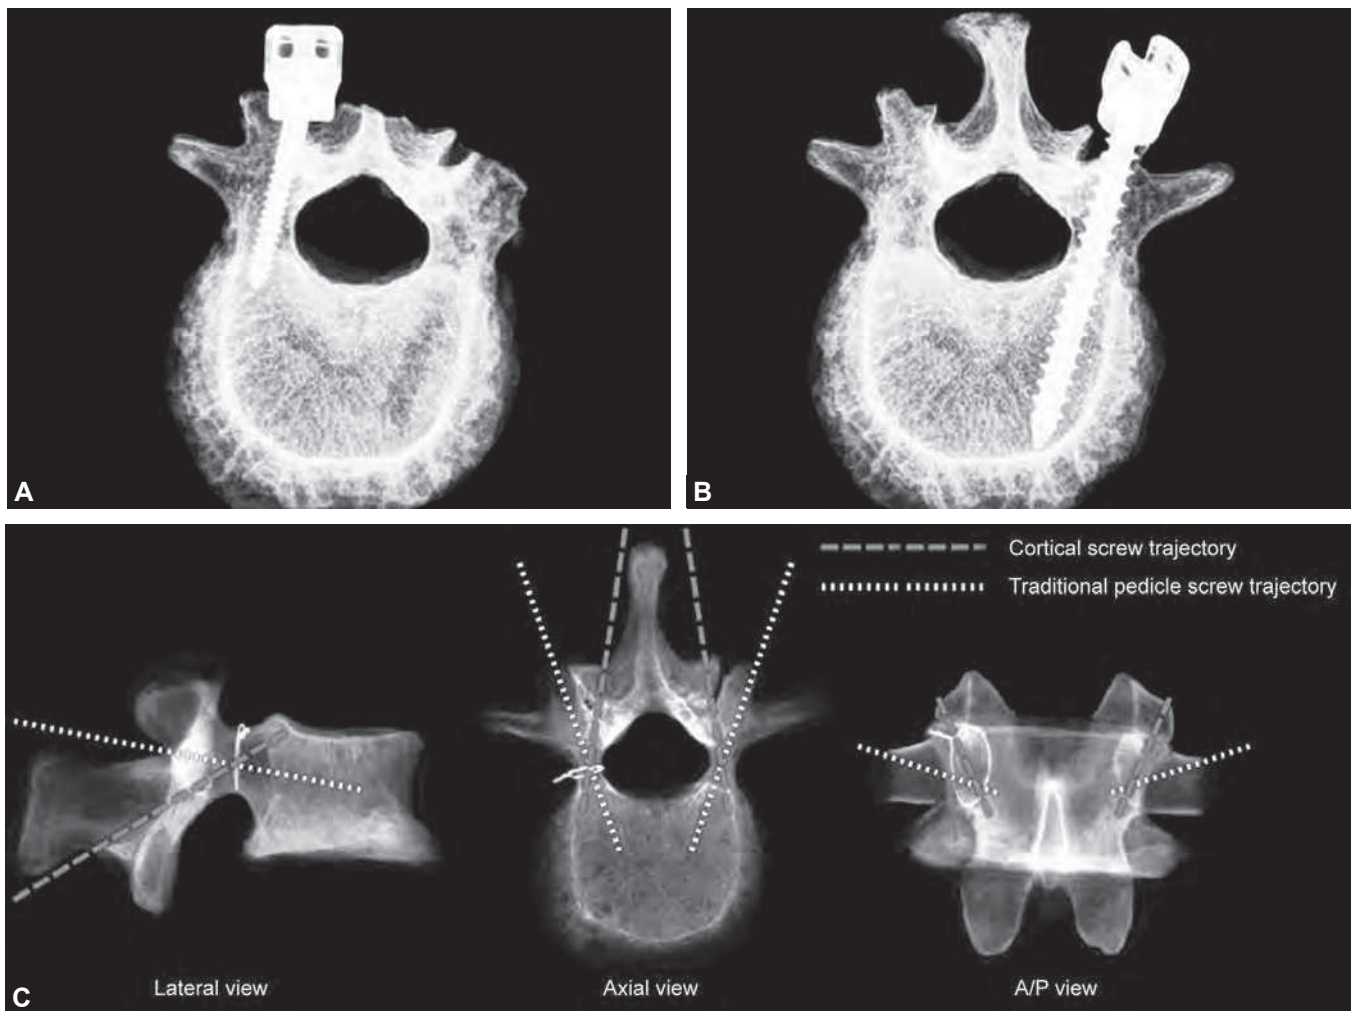

Kang et al. described a similar computed tomography (CT)-based percutaneous technique in patients for adjunctive fixation after an ALIF. The procedure was performed under conscious sedation, was an average duration of 43 minutes, and resulted in a successful fusion in all 17 patients.²³ Overall, either open or percutaneous TFS fixation safely improves construct stiffness in extension and axial rotation at one or two-levels, but nonetheless remains biomechanically inferior to PS.

CORTICAL SCREW FIXATION

Santoni et al. proposed a CS as a potential modification to the traditional anatomic PS trajectory. The CS has a more medial starting point with a trajectory that follows a caudocephalad path in the sagittal plane and a more lateral direction in the axial plane (Figs. 68.4A to C).

Instead of engaging trabecular bone within the vertebral body, the CS is secured by cortical bone from the pedicle and is anchored within the pars interarticularis. Lastly, unlike PS fixation, CS fixation requires interconnecting rods fastened with top-locking connectors.^{35,36}

Although the emerging technique requires a shorter screw (average 29 mm) with a smaller diameter (average 4.66 mm), Santoni et al. reported a trend ($p = 0.08$) towards 30% greater pullout strength for CS versus PS.³⁵ Of note, 20% of CSs placed had a breach of the medial wall of the pedicle seen on plain radiography and gross examination. In addition, the study offered limited information regarding the screw insertion technique. Perez-Orribo et al. recently published the first cadaver study to assess the segmental ROM of CS (4.5 mm) versus PS (6.5 mm) in an intact spine, in conjunction with a TLIF, and in association

Figs. 68.4A to C: These figures illustrate the cortical screw trajectory in the axial plane (A and B) and other planes (C).

with a direct lateral interbody fusion (DLIF). For an intact spine or a non-stabilizing TLIF, a traditional PS-rod system had slightly greater stiffness in axial rotation and lateral bending than CS-rod systems. However, CS systems may offer greater rigidity in flexion-extension. In conjunction with a DLIF, there were no significant differences in ROM between PS and CS.

Cortical screw fixation is postulated to become a clinically useful option to improve pull out strength in osteoporotic bone and has the advantage of less soft tissue dissection than PS systems. However, the more medial starting point and potential for medial pedicle wall violation may limit the utility of this technique. To date, minimal data is available in terms of a safe screw insertion technique that avoids medial pedicle wall violation. In addition, no studies have reported clinical results using this technique.

Pedicle screw fixation of the lumbar spine remains the gold standard for achieving rigid fixation from a posterior approach. While generally biomechanically inferior when used in isolation, transfacet, translaminar, and newly described CSs may offer a useful alternative for posterior fixation. These fixation options minimize soft tissue dissection, may reduce the risk of nerve root injury, and are undoubtedly cost advantageous. Biomechanical strength of alternative fixation constructs versus PS systems may be relatively similar when these systems are utilized as an adjunct after anterior or lateral interbody fusion cages. Clinical outcome data, however, remains limited.

KEY POINTS

- Pedicle screw fixation of the lumbar spine remains the gold standard for achieving rigid fixation from a posterior approach.
- Transfacet, translaminar, and CSs offer an alternative for posterior fixation.
- Alternative fixation techniques minimize soft tissue dissection, risk to adjacent nerve roots, and implant costs.
- Transfacet, translaminar, and CSs may be biomechanically similar to PSs when used as an adjunct to interbody fusion devices.
- To date, clinical outcome data remains limited.

HISTORY OF ANTERIOR LUMBAR INTERBODY FUSION

The first published description of an interbody fusion was the anterior lumbar interbody fusion (ALIF). Muller¹ is credited with this first use of ALIF, as a treatment for Pott's disease, in 1906. Capener² and Mercer³ subsequently adopted it for the treatment of spondylolisthesis. In 1933, Burns⁴ performed an interbody fusion for a traumatic L5-S1 spondylolisthesis via a transabdominal approach. None of these pioneering authors discussed intervertebral disc degeneration as an indication for performing ALIF.

Lane and Moore⁵ were the first authors to describe ALIF as a treatment for degenerative disease. Their 1948 publication is regarded as the first endeavor to popularize this procedure to treat symptoms attributable to lumbar intervertebral disc degeneration. Soon thereafter, in 1953, Cloward⁶ reported the outcomes of 262 patients with disc degeneration, sciatica, and back pain, who were treated with ALIF. Others continued to use the anterior approach for surgical treatment of lumbar tuberculosis, intervertebral disc degeneration, and spondylolisthesis during the 1950s and the 1960s, but the number of cases reported by surgeons was small.

Reports of the use of spinal instrumentation for anterior lumbar stabilization soon followed. Humphries et al.⁷ described an anterior lumbar compression plate with

unicortical screw fixation in 1961. While the early results were outstanding, subsequent authors reported less favorable results. For example, Stauffer and Coventry⁸ reviewed the Mayo Clinic experience and found a 56% overall "success" rate. This modest rate of success was not felt to justify the invasive nature of the procedure. For this reason, ALIF lost favor until the advent of cylindrical fusion cage in the 1980s.

In recent decades, ALIF has gained popularity. This is related, in part, to the proposed advantages of ALIF over posterior fusion. These include provision of a large fusion surface area, restoration of segmental height and alignment, and avoidance of damage to the posterior paraspinal musculature. In concert with the increase in ALIF use, novel implants were developed. The instrumentation used for the application of these implants was well designed and was typically "user friendly". These implants were used for a variety of indications by enthusiastic surgeons in what has been termed "the age of the cage". Spectacular results were initially reported.

In the early 1990s, minimally invasive lumbar spine surgery, intended to minimize soft-tissue damage, was introduced when the first laparoscopic lumbar discectomy was described by Obenchain in 1991.⁹ Laparoscopic ALIF was described in 1995 by Zucherman and colleagues.^{10,11} This technique, initially embraced with enthusiasm, was found to be technically challenging and has since been

replaced by mini-open techniques. Mini-open ALIF is typically performed through a small para-median abdominal incision, with dissection around the rectus abdominis muscle to access the retroperitoneal space. In 1997, Mayer¹² described the modified retroperitoneal and transperitoneal approaches to ALIF using microsurgical instruments. He concluded that these techniques are reasonably applicable from L2 to S1.

In some clinical scenarios, ALIF can be an adequate treatment, without posterior stabilization. It has been recognized, however, that this “stand-alone” strategy can be associated with a high rate of nonunion.^{13,14} For this reason, and also since there is biomechanical evidence to suggest that many ALIF cages do not provide adequate stability,¹⁵⁻¹⁷ several types of supplementary fixation have been introduced. These have included anterior plates, pedicle screws, facet screws, and translaminar screws.¹⁸⁻²² While ALIF is typically performed as part of a circumferential fusion, there is conflicting information regarding the potential benefit of the addition of posterior surgery. At least one modern clinical study evaluating stand-alone ALIF has shown suboptimal radiographic and clinical outcomes; the author suggested that additional benefit may be gained from adjunctive posterior stabilization.²³ Another prospective cohort study, however, concluded that stand-alone ALIF leads to better clinical results than anteroposterior lumbar fusion (APLF) in the treatment of degenerative disc disease.²⁴ Currently, it is unclear whether stand-alone cages are sufficient for ALIF and there is no consensus as to what degree of stability is required to guarantee a satisfactory clinical outcome.

SURGICAL ANATOMY

The anterior aspect of the lumbar spine is within the retroperitoneal space, dorsal to the abdominal cavity and its contents.^{25,26} The peritoneum contains the descending colon, kidney, and ureter. The visceral organs can typically be safely retracted without opening the peritoneum. The dome-shaped roof of the abdominal cavity is the thoracic diaphragm (a thin sheet of muscle under the lungs). The diaphragm bridges over the psoas and quadratus lumborum by the arcuate ligaments. The left crus of the diaphragm extends to the second lumbar vertebra, and attaches to the anterior longitudinal ligament.

The psoas occupies the space lateral to the lumbar vertebral bodies. Within the psoas lie the branches of the

lumbosacral plexus. The genitofemoral nerve lies on the ventral surface of the distal psoas belly. The nerve roots giving rise to the femoral nerve are found in the substance of the muscle, typically descending within the lateral aspect of the psoas in the lower lumbar region. The obturator nerve will be found along the medial edge of the psoas. The lateral femoral cutaneous nerve will exit the upper edge of the psoas and can be seen passing into the pelvis.

The aorta descends into the abdomen anterior to the body of the last thoracic vertebra. The inferior vena cava arises from the major lower extremity veins, which are the common iliac veins. The inferior vena cava ascends alongside the vertebral column, typically on the right. The aorta and inferior vena cava typically bifurcate anterior to the fourth lumbar vertebra. Therefore, the common iliac artery and vein are encountered in the surgical approach to the fifth lumbar vertebra. Segmental vessels pass in the axial plane, around each vertebral body, and are intimately associated with the periosteum.

Surgical Approaches to the Anterior Lumbar Spine

Anterolateral Retroperitoneal Approach to the Lumbar Spine

The retroperitoneal approach²⁵⁻²⁸ is appropriate for access to the mid-lumbar spine (L2-L5). A left-sided approach is typically preferred since manipulation of the thin-walled inferior vena cava is associated with higher risk than manipulation of the abdominal aorta. Furthermore, liver retraction is obviated by a left-sided approach. This anterolateral retroperitoneal approach can provide broad exposure of the lumbar spine with less risk to the viscera, great vessels, and sympathetic plexus, as compared to the transperitoneal approach.

In anticipation of surgery, a bowel prep is recommended to decompress the colon. The patient is positioned in a right lateral decubitus position; the left side is rotated upward 60°. This position is maintained with bolsters under the left hip and under the left shoulder. The articulation in the operating table should be used to extend the thoracolumbar junction. By increasing the distance between the lower ribs and ilium, the depth of retraction is reduced. Retraction is also facilitated by left hip flexion, which relaxes the ipsilateral iliopsoas muscle,

while the right leg is typically extended. When possible, the patient should be positioned with the operative vertebral end plates orthogonal to the floor. This makes intraoperative radiographs easier to interpret and removes a dimensional variable in planning placement of instrumentation.

Intraoperative radiographs are used to plan the location of the skin incision. Superficially, the latissimus dorsi and posterior serratus inferior are incised. The external oblique fascia is then identified, and the muscle is opened in line with the skin incision to the lateral border of the rectus fascia. The internal oblique and transversus abdominis muscles are then opened. The iliocostal muscle is partially divided posteriorly. The transversalis fascia is incised to enter the retroperitoneal space. The peritoneum can then be dissected from the abdominal wall, thus exploring the retroperitoneal space. Dissection of the more medial muscle layers and fascia is more difficult, and peritoneal tears can occur. Tears in the peritoneum are typically repaired. Posteriorly the peritoneum is dissected free from the inferior pole of the left kidney and from the posterior abdominal wall. A plane between the retroperitoneal organs (kidney and ureter) and the retroperitoneal musculature (quadratus lumborum and iliopsoas) is developed with blunt dissection. The retroperitoneal organs and peritoneal sac are retracted medially and toward the dependent side. This exposure can then be maintained with a self-retaining, broad-based, table-mounted retraction system, such as the Bookwalter or Omni retractor system. Fluoroscopy or plain radiograph is used to confirm the appropriate spinal level.

The psoas muscle is mobilized posteriorly using a Cobb elevator to expose the anterolateral aspect of the operative vertebrae. Care is taken to avoid unnecessary mobilization or retraction of the psoas. The fibers of the psoas muscle should not be transected. Care should be taken to avoid damaging the lumbosacral plexus within the psoas muscle. Neurological structures on the surface of the muscle should also be treated with caution: the genitofemoral nerve, which provides sensation to the scrotum and inner thigh, can be typically identified on the ventral surface of the muscle distal to L2. Additionally, the sympathetic trunk can typically be identified along the medial border of the psoas muscle. Monopolar cautery should not be used in this area, to reduce the risk of injury to the sympathetic trunk.

Segmental vessels are identified as the neural foramina are approached. These vessels can be ligated midway between the parent vessel and the foramen; ligation at this point may reduce the risk of vascular compromise of the neural elements. After the segmental vessels are secured,

the aorta and iliac vessels are mobilized to expose the ventrolateral surface of the vertebral bodies. The intended spinal procedures can then be performed. After removing the retractors, inspecting the retroperitoneal space, and ensuring meticulous hemostasis, the peritoneal and retroperitoneal contents are allowed to fall back into normal anatomic position. The abdominal muscle layers are closed anatomically and the skin is closed in the standard fashion.

Anterolateral Approach to the Thoracolumbar Junction and the Upper Lumbar Spine

In cases where exposure of the thoracolumbar junction and the upper lumbar spine (L1 and L2) is desired, the skin incision is curved proximally. The incision should reach two rib interspaces above the corresponding operative vertebrae. This is most typically the 10th or 11th rib, in order to provide access to the thoracolumbar junction. A subperiosteal rib resection is performed, and the resulting aperture is widened using a rib spreader. Care should be taken to preserve the intercostal neurovascular structures, particularly with retraction of the upper rib. The diaphragm is identified and mobilized. Its attachments are released circumferentially from the crus to the peripheral costal attachments. A 2-cm cuff or diaphragm should be preserved for reconstruction during closure.

Once the retroperitoneum is entered, exposure of the upper lumbar segments can be achieved by retracting the lower pole of the kidney medially and superiorly. The ureter is carefully mobilized, and the left diaphragmatic crus, which extends to the second vertebral body, is taken down. Exposure of the vertebral bodies can then be performed. The psoas muscle is retracted posteriorly at L1 and L2; the degree of exposure is dictated by the goals of the surgery. Care is taken not to retract the psoas excessively. Injury to the psoas can cause lumbar plexus adverse events such as postoperative leg weakness, numbness, and pain. At closure, the diaphragm is carefully reattached to the costal margin. The crus is reattached as well. One or more chest tubes are employed, and a pleural seal is reestablished. The tissues of the thoracic wall are then closed in anatomic layers.

Midline Incision Approaches to the Anterior Lumbar Spine

When bilateral exposure of the lumbar spine is desired, a midline incision can be used to perform either a retroperitoneal or a transperitoneal approach.²⁵⁻²⁸

The patient is positioned supine with the sacrum elevated either by a bolster or by gently extending the operating table. This position helps to displace the abdominal contents rostrally, extend the distance between the lower ribs and ilium, and reduce the anticipated retraction distance from the skin to the vertebrae. Intraoperative fluoroscopy can be helpful with regard to positioning. The anteroposterior projection is used to confirm that the patient is not rotated. The lateral projection can be used to plan the location of the skin incision, and to determine the angle of approach to a particular disc space. Oxygen saturation is monitored in both legs during the perioperative period, with a pulse oximeter placed on the great toe of each foot.

A midline, left-sided paramedian, or Pfannenstiel incision can be used. A midline incision along the linea alba may reduce the risk of rectus muscle denervation, as the rectus muscle is approached medially and is retracted laterally. An incision above the umbilicus typically allows exposure of L4 and above while an incision below the umbilicus allows exposure of L4 to S1. An exposure of the L5-S1 disc generally requires an incision just above the superior aspect of the symphysis pubis. The rectus sheath is entered, and the left rectus muscle is retracted. The transversalis fascia is exposed, and the plane of retroperitoneal approach is entered. Electrocautery is used with caution to cauterize deep epigastric vessels during blunt retroperitoneal dissection. The peritoneal sac is manually dissected from the abdominal wall. The inferior aspect of the posterior rectus sheath can be incised to accommodate exposure of deeper structures. A table-mounted, self-retaining retractor system, such as a Bookwalter or Omni retractor, is used to maintain the exposure.

The L5-S1 disc space typically lies below the aortic bifurcation. The superior hypogastric plexus is at direct risk here however, since it lies directly anterior to the L5 vertebral body and the L5-S1 disc space. Injury to the plexus can cause retrograde ejaculation (RE) in male patients. In order to reduce this risk, the prevertebral tissues, including the superior hypogastric plexus, are carefully mobilized en bloc by blunt dissection over the disc space. Monopolar cautery should not be used here; bipolar electrocautery or vascular clips are preferred in this area, also to reduce the risk of hypogastric plexus injury. The iliac vessels are retracted laterally to expose the L5-S1 disc space. The middle sacral artery and vein, if present, are ligated using clips and/or are cauterized using bipolar cautery.

The L3-4 and the L4-5 disc spaces are most typically approached by rightward mobilization of the great vessels. The lumbar segmental vessels are first ligated. Subsequently, in order to sufficiently expose beyond the midline,

the iliolumbar vein must be isolated and doubly ligated. This will then effectively accommodate mobilization of the great venous structures to the right, so that the right side of the disc can be accessed. The lymphatic channels may be encountered during this dissection, but generally with little clinical consequence. Retractors are placed to maintain the exposure of the disc space, with the vascular structures retracted to the right side. The intended spine procedures can then be performed between L3 and L5. When the retractors are removed, the peritoneal sac is allowed to fall back into anatomic position. The abdominal wall fascia is closed to prevent hernia. The posterior rectus sheath can be left unrepaired. The subcutaneous tissue and the skin are closed in layers.

Midline Incision Retroperitoneal Approach from the Right Side²⁹

The patient's position and preparation are as described above. Fluoroscopy is used to plan the skin incision. The skin incision is typically performed vertically, centered on the operative disc. The skin incision can also be performed horizontally, when only the L5-S1 disc needs to be exposed. The abdominal wall incision is then made vertically on the linea alba. The exposure then follows the medial edge of the right rectus abdominis muscle. This muscle is dissected upward and away from its posterior sheath, and below the arcuate ligament from the peritoneum. Blunt dissection is then performed laterally, pushing the peritoneum posteriorly. The peritoneum is then separated from the inner abdominal wall, working downward and underneath the posterior rectus sheath. This sheath can be incised vertically, from the arcuate ligament, depending on the level to be reached and on the patient's anatomy. The retroperitoneal space can then be accessed, and the peritoneal contents can be retracted superiorly, from right to left. To access the L5-S1 disc space, dissection is performed below the aortic bifurcation. Blunt dissection can be performed with a peanut sponge. Gentle sweeping of the soft tissue is performed from right to left. This tissue may contain the superior hypogastric plexus, and should be treated with care. The sacral vessels are then transected between clips.

To access L4-L5 and levels above, disc exposure will be centered between the medial edge of the right psoas muscle and the lateral edge of the vena cava. The right iliolumbar vein and the segmental vein above the disc are identified, ligated, and transected. In most cases, the

segmental artery may be preserved. The vena cava can then be gently retracted from right to left, providing adequate visualization of the disc and vertebral bodies involved. We have noticed that the majority of patients have a perforating vein, arising from the anterior aspect of L3 and L4 vertebral body, to join posterior to the vena cava. This vein should be coagulated and transected to allow retraction of the vena cava. These collateral venous branches have never been described previously. Once the vena cava can be retracted laterally, the spine will be adequately exposed to accommodate discectomy and implant. The closure follows with the surgical techniques described above.

Transperitoneal Approach to the Anterior Lumbar Spine

The transperitoneal approach can provide excellent bilateral exposure of the L5-S1 region.²⁵⁻²⁸ It also can be used for exposure of L4-5, but this is less favorable because of the typical location of the aortic bifurcation at that vertebral segment. The location of the aortic bifurcation can be determined preoperatively on cross sectional imaging. Mobilizing the great vessels to the right, after ligation of both the segmental lumbar vessels and the ascending lumbar vein, can provide exposure of the L3-L4 segment. The transperitoneal approach is contraindicated, however, in the presence of spinal infection.

A bowel preparation is employed the day before surgery, and broad-spectrum antibiotics are used preoperatively. The patient is positioned supine, with the pelvis elevated. This extended position allows the abdominal contents to shift into the upper abdomen. Fluoroscopy is used to identify the operative spinal segment (typically L5-S1) and to plan the incision. A midline or transverse incision may be used. Of note, the skin incision should be caudal to the umbilicus when exposing L5-S1. A small incision (<6 cm) can typically be used. The incision is performed in the midline and the approach follows through the subcutaneous tissues, fascia, and peritoneum. After the abdominal contents are retracted rostrally, the exposure is maintained with a table-mounted, self-retaining retractor such that the posterior peritoneum is exposed. The pelvic portion of the colon and its mesentery are retracted to the left, and the ureters are identified and protected. The posterior peritoneum is incised in the midline. The peritoneal opening is then extended caudally past the aortic bifurcation by following the course of the right common iliac artery to its bifurcation at the external and internal iliac arteries. This

provides access to the retroperitoneal space. Care should be taken to identify and protect the right ureter where it crosses the right external iliac artery.

The L5 vertebral body, L5-S1 disc space, and sacral promontory are easily palpated and can be well visualized below the aortic bifurcation. The prevertebral tissues, including the hypogastric plexus and the middle sacral artery, are identified and mobilized laterally. Retrograde ejaculation can result from injury to the hypogastric plexus; monopolar cautery should be avoided to reduce this risk. When a large left common iliac vein hinders access to the body of L5 and the sacral promontory, it must be mobilized and protected before proceeding to the discectomy. It is important to note that the left iliac vein occasionally can appear as a flat, white, bloodless ribbon across the L5-S1 disc space. Once well exposed, retractors are placed to maintain the access to the L5-S1 disc space.

The transperitoneal approach can be used to expose proximal to L5-S1, but significant vascular dissection and mobilization is required. For this reason, the retroperitoneal approach is a more appropriate choice for accessing more proximal levels of the spine.

At the conclusion of the spinal procedure, the posterior peritoneum is closed with 3-0 polyglactin 910 (Vicryl) suture, the bowel and omentum are returned to their normal anatomic position, and the abdominal fascia and anterior peritoneum are closed with interrupted sutures. The subcutaneous tissue and skin are closed. Postoperatively an ileus should be expected.

Minimally Invasive Approaches

Laparoscopic and Endoscopic Approaches to the Anterior Lumbar Spine

Laparoscopic and endoscopic techniques require additional equipment and special operating room setup and are associated with a steep learning curve.^{26,27,30-36} Laparoscopic ALIF can be used as a stand-alone procedure, or it can be combined with posterior instrumented fusion using either minimally invasive or open techniques.

Laparoscopic or Endoscopic Retroperitoneal Approaches

The endoscopic retroperitoneal approach was developed for urological surgery. McAfee and colleagues adapted it to be used for lumbar spine fusion. The procedure can be performed using CO₂ insufflation, balloon insufflation (gasless), or a combination of both techniques.

The patient is typically placed in the lateral decubitus position, but LeHuec has also described the approach performed in the supine position. A 2- to 3-cm transverse skin incision is created, centered on a line between the 11th rib and the anterior superior iliac spine. Blunt dissection is carried down through the abdominal muscle layers using an endoscopic trocar until the fatty retroperitoneal space is reached. Once the retroperitoneal space has been manually confirmed, the dissection balloon placed and then inflated creates a retroperitoneal cavity. At this point the balloon is removed and a self-retaining retractor system or CO₂ insufflation is used to maintain the retroperitoneal cavity. A minimum of three ports is placed; these are for retractors, endoscope, and working instruments. Once the appropriate level has been confirmed fluoroscopically, the psoas muscle is elevated from the spine. The discectomy and fusion are then performed.

Laparoscopic and Endoscopic Transperitoneal Approach

The laparoscopic transperitoneal approach can also be used to gain access to the lower lumbar spine. Special attention to the preoperative setup is necessary to increase the efficiency of the surgeon using this approach. The C-arm monitor and the video monitor are positioned to allow the surgeon an optimum view of both. The patient is placed supine on a radiolucent table. The pelvis is elevated to accentuate lordosis at the lumbosacral junction and the knees are flexed. Straps are placed on the patient's ankles to prevent sliding; a steep Trendelenburg position is required during the procedure to displace the abdominal viscera rostrally out of the pelvis. A nasogastric tube and Foley catheter are placed to decompress the stomach and bladder, respectively.

A small incision is made above the umbilicus. A Veress needle is carefully placed into the peritoneal cavity, which is insufflated with CO₂ to 10–15 mm Hg. This allows for insertion of a 10-mm portal through the same incision. A laparoscope is inserted through the trochar and the contents of the cavity are inspected. The endoscope can be manually controlled or in some cases manipulated by a voice-controlled robotic arm (AESOP 2000, Computer Motion, Goleta, CA). Using a 30°-angled laparoscope, two 5-mm secondary portals are placed under direct endoscopic visualization through the patient's right abdominal wall. A single 5-mm portal is placed in the left abdominal wall through which a fan retractor is placed. The sigmoid

colon is retracted to the patient's left using a suture attached to a Keith needle, which is passed through the abdominal wall, looped through the sigmoid mesentery, and passed back through the abdominal wall adjacent to the first puncture. The suture is then tied externally. The posterior peritoneum is divided at the base of the sigmoid colon using sharp dissection. The middle sacral artery and vein are identified, isolated, and transected. The presacral autonomic plexus is swept laterally using blunt dissection. Use of unipolar cauterization should be avoided in this area since it has been associated with autonomic plexus nerve injury and RE. The disc space of interest is identified fluoroscopically and laparoscopically. After a generous exposure of the anterior spinal column, a suprapubic incision is made and a special trochar is placed through the abdominal wall. The position of the suprapubic incision and portal is determined using the fluoroscopic C-arm in the lateral position. The plane of the disc space in the anteroposterior dimension is projected to the suprapubic region.

Mini-Open Retroperitoneal Approaches^{12,34,37}

Lateral Mini-Open Approach to L2 Through L5

This left-sided approach is performed with the patient in a lateral position. The operating table is rotated 20°–40° toward the surgeon, who is standing at the back of the patient. Lateral fluoroscopy is used to project the disc space onto the skin, and the AP fluoroscopy is used to mark the center of the disc space as well. The approach is started with a 4-cm skin incision centered above this projection in an oblique direction. The muscle fibers of the lateral abdominal wall (external oblique, internal oblique, and transversalis) are bluntly separated to expose the retroperitoneal space. The retroperitoneal space should be entered through the transverse abdominal muscle far lateral to avoid penetration of the peritoneum, which is typically less adherent to the lateral aspect of the abdominal wall. Blunt dissection is performed with cottonoids and modified Langenbeck hooks to expose the psoas muscle. The spine is then inspected, following the anteromedial "slope" of the psoas muscle. The genitofemoral nerve, which passes along this part of the psoas muscle, must be preserved. The anterolateral attachments of the psoas muscle are sharply dissected from the lateral circumference of the disc space, thus exposing the anterolateral aspect of the anterior longitudinal ligament.

The disc space is then confirmed by fluoroscopy, and blunt dissection is used to expose 5–10 mm of the adjacent vertebral bodies. At L4–L5, the left common iliac vein may obstruct the anterior medial angle of the surgical field and should be mobilized bluntly.

A frame-type retractor, with independently adjustable blades, maintains the surgical exposure. Two anchoring screws are inserted through drill holes in the adjacent vertebral bodies and serve as an anchor for the retractor. The anterolateral circumference of the segment to be fused is now exposed, which offers various options for anterior interbody fusion. For example, we perform 270° fusion, including posterior instrumentation, in most of our patients. In this setting, we prefer to use autologous iliac bone graft, which can be harvested through the same skin incision, and before introduction of the retractor. Other types of anterior interbody fusions are possible, however, including the use of homografts or allografts. The graft is mounted to a graftholder and impacted in “press-fit” fashion into the intervertebral space. Additional cancellous bone, harvested from the iliac crest as well as from the vertebral bodies, is impacted into the intervertebral space.

Midline Microsurgical Approach to L5-S1

Either the transperitoneal or the retroperitoneal approach can be used to expose the lumbosacral junction through this midline approach. In either case, the patient is positioned supine. Trendelenburg position is applied with the pelvis elevated, the lumbar spine hyperextended, and both hips abducted.

Lateral fluoroscopy is used to mark the orientation of the L5–S1 disc, to plan the skin incision. A “corridor line” is drawn onto the abdomen, and a 4-cm skin incision (longitudinal or transverse) is performed on (or centered on) the midline of the abdomen, overlying the planned corridor to L5–S1. The operation can be performed with a surgical microscope, or with headlamp and loupes. The surgeon stands between the legs of the patient.

The peritoneum is exposed by sharp dissection of the rectus sheath (linea alba) in the midline. In slim patients, the anterior circumference of L5–S1 can be exposed by blunt retroperitoneal dissection along the abdominal wall on the right side, crossing the common iliac artery and vein as well as the ureter. The prevertebral soft tissue, including the fibers of the superior hypogastric plexus, is gently pushed from the right to the left side. Thus, the major branches of the plexus can be preserved. Similar to other anterior

lumbar approaches, monopolar cautery should be avoided and the use of bipolar coagulation should be restricted to a minimum. The median sacral vessels are exposed, clipped, and dissected. In obese patients, the transperitoneal route may be preferred. In this instance, the peritoneum is exposed, split in the midline, and armed with sutures. The mesentery with the ileum is carefully pushed into the upper left abdominal cavity with sponges. The sigmoid colon is carefully retracted to the left. A soft tissue retractor such as the Miaspas mini ALIF retractor (Aesculap GmbH & Co., Tuttlingen, Germany) is placed such that the promontory is well visualized. The parietal peritoneum is incised with micro scissors in a craniocaudal direction. The semicircular incision is started approximately 5 mm medial to the right common iliac artery. The retroperitoneal fat tissue with the superior hypogastric plexus is exposed, bluntly dissected, and carefully retracted to the left side as described above. The middle sacral artery and vein, if present, can be ligated using clips or cauterized using bipolar cautery. The retractor can then be inserted under the parietal peritoneum, exposing the anterior aspect of the vertebral column.

Anterior Interbody Fusion Techniques

Disc Space Preparation

The anterior longitudinal ligament can be divided in an H-shape, and then bluntly dissected from the anterior aspect of the annulus fibrosus. The annulus fibrosus is then incised so that the interbody material can be removed. The endplates are prepared with curettes, taking care to maintain the structural integrity of the vertebrae. It is important that the discectomy be completed back to the posterior longitudinal ligament. Release of the posterior annulus is helpful so that balanced interbody distraction occurs throughout the disc space and not just anteriorly. This is particularly relevant in cases of significant disc space collapse. Herniated disc material may be retrieved through posterior annular defects. To assist with interbody access, interbody space distracters can be impacted unilaterally. After complete discectomy, resection of endplate cartilage, exposure of bleeding subchondral bone, and posterior release, the disc space may be ready for implant insertion.

Implant Insertion and Instrumentation

Implant selection and application is specific to the clinical scenario, and to the implant being used. In any case,

radiographic confirmation should be considered to ensure appropriate placement of the implant(s). The reconstruction of the interbody space should be performed to achieve anatomic restoration of interbody height and alignment in both the coronal and sagittal planes, when possible. While restoration of the foramen volume and alignment can be helpful in providing indirect neurological decompression, care to not “overstuff” the interbody space (or create a super-anatomic height restoration) may reduce the risk of adverse postoperative neurological symptoms. In the case of posterior element deficiency, such as pars lysis or posterior element fracture, the stability of an anatomically sized interbody device may be augmented by anterior instrumentation, to avoid “overstuffing” the interbody space.

■ INDICATIONS FOR ANTERIOR LUMBAR INTERBODY FUSION

As compared with the posterior interbody fusion procedures, ALIF provides direct access to the anterior elements of lumbar spine, allowing for complete disc excision and lumbar column manipulation. Because the vertebral body provides 90% of the articular surface area of the lumbar segment and supports 80% of the spinal load,³⁸ ALIF offers considerably larger bone surface area in a biomechanically compressive environment appropriate for fusion. It also offers an opportunity to reduce segmental deformity with annular releases, thereby relying on apophyseal bone for reconstruction. These reasons are among those used to explain why ALIF may offer improved fusion rates, as compared to posterior element fusion alone. Other theoretical advantages of ALIF over posterior fusion include direct removal of the interbody pathology, disc height restoration, less risk to the nerve roots and dura, and restoration of segmental coronal and sagittal alignment. With these proposed advantages, ALIF is helpful in cases of segmental instability such as posterior element deficiency, particularly at the lumbosacral junction, for treatment of deformities, unstable fractures, infections, and tumors or other infiltrative lesions causing significant segmental instability.

Treatment of Trauma with ALIF

Anterior lumbar interbody fusion was applied to lumbar trauma in an early stage of its development,³⁹ but did not gain significant popularity until the emergence of anterior instrumentation and other implants that could reliably provide circumferential reconstruction. From the anterior approach, vertebral corpectomy or discectomy, followed by direct decompression of the spinal canal can be achieved.

Subsequent restoration of anterior column stability can also be achieved, including with reestablishment of the normal sagittal and coronal alignment.^{40,41} Anterior structural support can be provided by allograft, autograft, or prefabricated implants. Some authors⁴² regard significant reconstructive anterior instrumentation to be technically challenging because of the major vessels and their relationship to the potentially bulky instrumentation. An alternative choice is to achieve decompression and interbody reconstruction from an anterior approach, followed by posterior instrumentation and fusion.

Treatment of Infection with ALIF

The anterior approach can be well suited to treat various infectious pathologies of the lumbar vertebral body and disc. Discitis and osteomyelitis compromise the stability of the anterior and middle columns. Structural consequences include deformity and functional instability. Back pain and neurological sequelae can also develop from epidural abscess. Common infectious causes of osteomyelitis include gram-positive bacteria (especially *Staphylococcus aureus*), and, less often, tuberculosis. Roughly half of all spinal osteomyelitis infections occur in the lumbar region.

Surgical intervention is indicated when there may be significant deformity, neurological deficit, and in cases that are refractory to medical management. The anterior approaches can provide access to the infected focus and, as such, is very effective for debriding the infected tissue. Furthermore, the anterior approach is well suited to reconstruction of the tissue defect. For these reasons, it has been adopted by many surgeons.^{27,43-45} Several reports have suggested that posterior stabilization should follow an anterior aggressive debridement and anterior reconstruction of the lumbar segment(s).^{44,46}

Treatment of Degenerative Disease with ALIF

The most common use of ALIF may be in the treatment of degenerative lumbar disorders. These include a variety of problems, such as discogenic back pain, degenerative deformity such as scoliosis and spondylolisthesis, herniated discs, and other degenerative deformities.⁴⁷ Anterior lumbar interbody fusion was first used in the treatment of degenerative disease in 1948.⁵ Since that time, several studies have reported ALIF to be safe and effective in relieving degenerative radicular and back pain.⁴⁸⁻⁵¹ Some surgeons have suggested that stand-alone ALIF is a viable

option for the treatment of patients with one- or two-level painful disc disease.^{50,51} It is widely recognized, however, that spinal fusion performed for the treatment of degenerative lower back pain is plagued by a poor predictability of pain relief. For treatment of a degenerative deformity, standalone ALIF may not be adequate, and correction of rigid curves typically requiring a combined anterior and posterior approach may be indicated.^{51,52} In the treatment of such deformities, particularly at the lumbosacral junction, the use of structural interbody grafting may improve the fusion rate, improve stability and sagittal balance, decreases strain in posterior instrumentation, and prevent implant failure.⁵²⁻⁵⁶ Several studies have reported that adult patients with spinal deformities can significantly achieve promising clinical outcomes when ALIF was used in conjunction with posterior instrumented fusion.⁵⁷⁻⁶⁰

Treatment of Isthmic Spondylolisthesis with ALIF

Traditionally, isthmic spondylolisthesis cases are categorized according to the severity of the displacement, as either low-grade (grade I and II) or high-grade (grade III and IV). Patients with low-grade isthmic spondylolisthesis often can be adequately treated nonoperatively. Surgery is indicated, however, if symptoms are disabling or in cases of significant or progressive neurologic symptoms. Fusion is a typical component of the surgical treatment for either low-grade or high-grade spondylolisthesis. Many surgeons have recommended ALIF for isthmic spondylolisthesis, particularly at L5-S1, with its ability to increase the intervertebral height and provide indirect decompression of the foramen, permanently while preserving or improving the segmental lordosis.⁶¹⁻⁶³ Clinical studies also have verified the effectiveness of ALIF in stabilizing the listhesis and alleviating the associated symptoms.^{51,63-67} ALIF has frequently been used in combination with posterior instrumented fusion, especially in the treatment of high-grade isthmic spondylolisthesis, which may help achieve the most reliable fusion and a successful clinical outcome.^{51,63-70}

Treatment of Iatrogenic Problems with ALIF

Iatrogenic lumbar pathologies that may be amenable to treatment with ALIF include instability or deformity related to prior surgery, adjacent segment disease with instability, construct failure, and pseudarthrosis.

While recurrent disc herniation may not be universally regarded as an iatrogenic problem, it has been treated with

ALIF. Vishteh and Dickman⁷¹ reported on anterior lumbar microdiscectomy and interbody fusion for the treatment of recurrent disc herniation in 2001. Choi et al.⁷² found ALIF to be an effective procedure with satisfactory clinical results in selected patients with a recurrent lumbar disc herniation.

Failed back surgery syndrome (FBSS) is a term that has been used to describe patients who have pain unresolved by prior surgical intervention. Coventry and Stauffer^{73,74} first described the use of anterior interbody fusion for treatment of FBSS. They reported good results for patients who underwent ALIF for treatment of FBSS. Subsequent surgeons also reported satisfactory reduction in back pain following ALIF performed at levels of previous posterolateral fusions⁷⁵⁻⁷⁷ Fujimaki and colleagues⁷⁸ reported a 97% fusion rate in 38 salvage cases treated with ALIF without instrumentation. In 1997, Kostuik⁷⁹ described 51 patients who had undergone revision anterior instrumented interbody fusion. The clinical success rate approached 70%, and the reported incidence of subsequent pseudarthrosis was 9%. Kuslich and colleagues⁸⁰ similarly reported a 96% fusion rate and a 70% clinical success rate in a group of 76 patients who underwent anterior fusion with stand-alone Bagby-Kuslich cages, after prior decompression. Results of Duggal et al.⁸¹ resonated with these previously published series, demonstrating statistically significant improvements in back pain, leg pain, and functional status. Albert and colleagues⁸² reported in 2000 on 37 consecutive patients with symptomatic lumbar pseudarthrosis who underwent combined APLFs. Significantly improved radiographic and functional results were reported in this case series.

Flat-back syndrome typically is an iatrogenic problem, characterized by forward sagittal imbalance, and frequently observed in patients who underwent posterior scoliosis fusion with early distraction-type instrumentation. It also can occur, however, with modern fusion techniques.⁸³ The surgical treatments of these complex imbalances can be challenging. LaGrone et al.⁸⁴ showed that anterior fusion results in a higher fusion rate and a lower amount of sagittal plane imbalance. Circumferential fusions frequently are reasonable choice.⁵¹

Treatment of Segmental Deformity with ALIF

Anterior lumbar interbody fusion can be applied to other spinal deformity conditions. Anterior instrumented fusion

has been used for many years in the treatment of adolescent idiopathic scoliosis (AIS). The anterior approach can facilitate deformity correction including derotation, can help maintain lumbar lordosis, reduce the number of fused segments, and can reduce operative blood loss.⁸⁵⁻⁹¹ Anterior lumbar interbody fusion can also be a helpful reconstruction and fusion adjunct to posterior deformity surgery, particularly when a long fusion to the sacrum is performed. The additional use of dual rod systems with interbody cage and graft has been associated with a relative decrease in instrumentation failures, loss of correction, and pseudarthrosis.⁹²⁻⁹⁴ Recent evidence also suggests that the anterior approach in the treatment of thoracolumbar and lumbar curves in AIS offers good long-term clinical outcomes.⁹⁵

■ CONTROVERSIES RELATED TO ANTERIOR LUMBAR INTERBODY FUSION

Stand-alone Anterior versus Combined Anterior/Posterior Instrumentation

One attractive attribute of ALIF is the potential to achieve interbody fusion without requiring posterior muscle dissection or exposure of the neural elements. The early attempts at using this anterior only strategy were met with certain shortcomings, however. The early clinical results using anterior interbody autograft or allograft (alone) were poor.⁸ Dennis et al.⁹⁶ reported their experience in treating 31 consecutive patients with ALIF using both iliac allograft and autograft bone in the interbody space. They reported that 100% of their patients demonstrated postoperative disc space height loss, to at least the preoperative height. A significant fraction of their patients (46%) developed postoperative interbody height less than their preoperative height. Watkins⁹⁷ also noted that autogenic iliac crest tricortical grafts typically exhibited partial resorption, which was associated with loss of interbody height, as well as subsidence, before healing. The recognition of these shortcomings motivated the development of interbody cages and other implants.

The stability of a stand-alone interbody device depends primarily on the compressive forces produced by tension engendered in the remaining annulus fibrosus. The magnitude of this compressive force reduces by 25%; however, 15 minutes after the initial device insertion, due to relaxation of the annular fibers.⁹⁸ This observation helps

to explain why stand-alone ALIF procedures have been seen to exhibit a wide variety of fusion rates, and to exhibit potential for subsidence and migration.^{99,100}

The design of the interbody device greatly affects biomechanical stability. Andreou and colleagues¹⁰¹ compared the initial segmental stability of five stand-alone ALIF interbody devices (I/F, BAK, TIS, SynCage, and ScrewCage) in a human cadaveric study. They reported a reduction in the range of motion (ROM) and an increase the neutral zone (NZ) in all loading directions. The BAK and TIS cages demonstrated the largest NZ increase in flexion/extension and lateral bending. The degree of geometrical cage-end plate surface mismatch was responsible for the differences in NZ between cages. Cages with sharp teeth were found to exhibit greater pullout forces. Both the height and the sagittal profile of the devices influenced the initial stability. The residual ROM was found to be related to the degree of micro-motion at the cage-end plate interface. Various types of internal fixation, such as anterior plates,¹⁰³⁻¹⁰⁶ pedicle screws^{102,104-108} and translaminar screws,^{103,107,109} can augment the stability of stand-alone ALIF by decreasing the ROM and increasing the stiffness of the segment. Kim et al.¹¹⁰ performed a finite element analysis investigating motion and stress at the bone-implant interface in a model of ALIF augmented with pedicle screw fixation (PSF). They reported that the addition of PSF to the stand-alone ALIF was associated with greater segmental stiffness, reduced relative motion, reduced bone deformation, and reduced bone stress at the cage-bone interface. They concluded that geometric constraints imparted by PSF substantially reduced the stress and the motion, and may contribute to improved bone ingrowth at the bone-cage interface, compared with the stand-alone ALIF.

Stand-alone ALIF with interbody allograft or autograft may be associated with subsidence of the interbody graft and loss of segmental lordosis. With the advent of cages, many investigators reported a relative decrease in the degree of subsidence, and better maintenance of segmental lordosis. Choi et al.¹¹¹ reported the results of using paired stand-alone rectangular cages; despite a reduction in disc height compared to that seen with the initial intraoperative distraction, the disc height at the final recent follow-up was significantly greater than that measured preoperatively. Hsieh et al.¹¹² examined pre- and postoperative interbody height and alignment in patients who underwent either ALIF or transforaminal lumbar interbody fusion (TLIF). For the ALIF group, they reported an increase in segmental lordosis from 7.1° to 15.4°, and an increase of

65% in disc height after surgery. McAfee et al.¹¹³ also measured the interbody height before and after L4/L5 ALIF using Bagby and Kuslich cages. While they reported an initial subsidence (12% loss of interbody height between the intraoperative and the 24 months radiograph), they also reported an overall increase of approximately 60% between the preoperative and final (24 months) measurement. Pavlov et al.¹¹⁴ reported radiologic results in 42 patients who had undergone one or two-level ALIF with SynCage and supplemental posterior fixation with trans-laminar or pedicle screws. Average intervertebral height was improved from 8.7 mm to 17.6 mm. The average lordosis was also increased (10.6° for the fused segment).

Anterior lumbar interbody fusion appears to offer excellent improvement in interbody height and alignment. The study by Niemeyer et al.¹¹⁵ supported this, and furthermore reported that ALIF may offer better interbody reconstruction than TLIF. This study compared ROM and NZ following interbody reconstruction by either ALIF or TLIF. In both the stand-alone scenario, and following supplemental posterior PSE, ALIF provided better segmental stability than TLIF cage in flexion-extension and in axial rotation.

The fusion rate for stand-alone ALIF varies considerably from one study to another. Most authors agree, however, that supplemental fixation with ALIF provides a better biomechanical environment, and may result in an improved fusion rate. Naffis et al. reported the fusion rates measured by thin-section CT in four ALIF cohorts: 25 cases with stand-alone ALIF (51% fused); 15 ALIF with trans-laminar screws (58% fused); 17 ALIF + unilateral pedicle screws (89% fused, $P < 0.01$) and 24 ALIF + bilateral pedicle screws (88% fused, $P < 0.01$).

The reported clinical results following ALIF have also been variable. Furthermore, several ALIF clinical studies have shown no correlation between clinical outcomes and fusion rates.^{63,116,117} Recently, Li et al.²³ reported on the safety and efficacy of the anterior Carbon I/F Cage used in 112 patients who underwent single-level ALIF. They concluded that the anterior I/F Cage is a safe surgical option in the treatment of single-level lumbar degenerative disc disease. As a stand-alone construct, the I/F Cage yielded suboptimal radiographic and clinical outcomes, however. The authors suggested that additional benefit might be gained from supplemental posterior stabilization. Strube et al.²⁴ enrolled 80 patients in a prospective cohort study comparing single-level ALIF with APLF. In contradistinction to other studies, they found that stand-alone ALIF was

associated with better clinical results than APLF. There were no differences seen in fusion rate 41 months after surgery. They suggested that if a posterior approach is not needed for decompression or reduction, a stand-alone ALIF might be a favorable strategy.

While successful arthrodesis is one goal following ALIF, successful fusion does not always correlate with a successful clinical result. It currently is unclear whether stand-alone ALIF is sufficient for arthrodesis and what degree of stability is required to guarantee a satisfactory clinical outcome.

Open versus Minimally Invasive ALIF

There is less controversy regarding the relative benefits of open and minimally invasive ALIF. Since the development of the original open ALIF, the technique has been modified several times. Minimally invasive spine surgery is becoming more frequently used, in part due to the reported benefits. These benefits include decreased muscle damage, shorter hospitalization time, and quicker recovery.

Minimally invasive ALIF includes the laparoscopic and mini-open procedures. While there are theoretical advantages of minimizing soft-tissue damage during the ALIF exposure, the number of studies published regarding minimally invasive ALIF is still small. Saraph et al.¹¹⁸ conducted a retrospective study comparing conventional (open) with the mini-open extraperitoneal approach; surgical time and blood loss were reduced with minimally invasive extraperitoneal ALIF. They also reported a significant improvement in postoperative back pain in the minimally invasive group, while all other clinical parameters showed no significant difference. Zdeblick and David³⁴ prospectively compared laparoscopic ALIF with mini-open ALIF; they were not able to find a difference in operative time, blood loss, or length of hospital stay for one-level fusions. The laparoscopic approach, however, had a higher complication rate, and a slightly longer operative time when used for two level cases. Similarly, in a retrospective study, Kaiser et al.¹¹⁹ found no difference in blood loss, but operative times were significantly longer for L5/S1 laparoscopic ALIF procedures (173 minutes compared with 145 minutes), and length of hospital stay was shorter (2.8 days compared with 3.5 days). Importantly, for L5/S1 fusions, they reported a significantly higher rate of RE for laparoscopic ALIF procedures compared with mini-open ALIF (45% compared with 6%). Chung et al.¹²⁰ retrospec-

tively reported that operative time was significantly longer for laparoscopic ALIF procedures (158 minutes compared with 83 minutes), although blood loss and length of hospital stay were not significantly different. In this study, clinical and radiographic outcomes were similar after 2-year follow-up. Based on these reports, in part, the general trend appears to be moving away from laparoscopic/endoscopic procedures, and toward mini-open procedures.

COMPLICATIONS

Anterior lumbar interbody fusion complications can be categorized as either intraoperative or postoperative. The postoperative complications can be sub-divided into the early late events. Complications also can be classified by system, such as visceral, vascular, neurologic, incision and graft related.

Most intraoperative complications are approach-related. Perforation of the peritoneum during a retroperitoneal approach is not uncommon. Urinary bladder, ureter, and gastrointestinal injuries may occur by misplaced retractors or overaggressive retraction. Misplaced hardware may result in neurologic or vascular injury; dural tears and nerve root injury have been reported¹²¹ as well as catastrophic bleeding.¹²²⁻¹²⁵ The superior hypogastric plexus that innervates the internal vesicle sphincter controls the normal ejaculatory reflex; this plexus can be damaged during anterior lumbar exposure, resulting in RE. Use of monopolar electrocoagulation¹²⁶ in the area of the anterior lumbar spine has in particular been implicated in injury to the superior hypogastric plexus. This is discussed in more detail below. Early postoperative complications include ileus, infection, hematoma, deep vein thrombosis, transient and permanent nerve injury, while late complications include hardware failure, bone resorption, adjacent segment disease (ASD) and pseudarthrosis.

Vascular injury can be a serious complication, often associated with considerable morbidity. Previous literature suggested that the most common vascular injuries are tears and lacerations of the aorta, iliac veins, and vena cava, with injury rates ranging widely from 0% to 18.4% in various studies.¹²²⁻¹²⁹ An indirect vascular complication is ischemic injury, such as that caused by partial or complete occlusion of the left iliac artery due to retraction.¹³⁰ Ischemic complications have also developed from the formation of thrombosis within this vessel and its branches, also typically attributed to forceful or prolonged retraction.^{124,131-136}

Dural tear is not an uncommon complication during ALIF; the incidence has been reported to be >10%.^{83,137} The incidence of neurologic complications, however, is difficult to determine owing to differences in how these complications are defined. Kuslich et al.⁸⁰ reported persistent neurologic symptoms in 2.0% of ALIF cases using BAK cages, while Scaduto et al.¹²³ reported 1% rate of neurologic injury using a threaded cylindrical cage.

The reported incidence of RE after ALIF varies widely in the literature.¹³⁸ A large worldwide survey of surgeons published in 1984 reported that the incidence of RE was rare (0.42%).¹³⁹ Other studies reported higher incidences, particularly those studies evaluating the laparoscopic transperitoneal approaches.^{33,140-143} While Tiusanen et al.¹⁴⁴ indicated that RE occurred only after a transperitoneal procedure, Flynn and Price¹³⁹ concluded that the approach (transperitoneal vs. retroperitoneal) was not related to the risk of RE. In one prospective study, Sasso et al.¹⁴⁰ reported the transperitoneal approach to be associated with a 10-fold greater risk of postoperative RE than the retroperitoneal approach. Carragee and colleagues¹⁴⁵ retrospectively compared the incidence of RE in patients who had previously undergone ALIF with and without rhBMP-2 (Infuse). Their retrospective chart review revealed that 5 of the 69 (7.2%) patients treated with rhBMP-2 experienced postoperative RE compared with 1 of the 174 patients (0.6%) treated with autograft. In another retrospective cohort study, Lindley and colleagues¹⁴⁶ reviewed 95 patients who underwent L5/S1 retroperitoneal ALIF. They reported that 4 of the 54 (7.4%) rhBMP-2 patients experienced postoperative RE. They also found, however, that 4 of the 41 (9.8%) patients treated with anterior disc replacement (ADR) [and without bone morphogenetic protein (BMP)] by the same surgical approach had postoperative RE. They suggested that retroperitoneal approach rather than the use of BMP seems to be responsible for this risk.

In comparison to the traditional open approach ALIF, laparoscopic/endoscopic or mini-open ALIF may be associated with a significantly higher rate of complications. Escobar et al.¹⁴⁷ reported an 18% incidence of neural injury and 25% incidence of RE. Twenty-five (11%) of these cases had to be converted to open procedures because of intraoperative complications. Regan et al.³³ reported a 19.1% complication rate for laparoscopic procedures as compared to 14.1% for open ALIF procedures. Zdeblick and David³⁴ also reported significantly higher complication rates in patients undergoing laparoscopic ALIF (20%) as compared to open (4%) at the L5/S1 level.

Adjacent segment disease is one potential late complication related to ALIF. There are limited investigating ASD following ALIF, but a few conclusions can be derived from studies with longer term follow up. In a retrospective study, Min and colleagues¹⁴⁸ compared patients that developed ASD to patients who did not develop ASD following anterior or posterior instrumented lumbar fusion at L4-L5. He reported that the proportion of patients who underwent ALIF in the non-ASD group was 77.8% as compared to 36.7% in the ASD group. This suggests that ALIF (alone) may reduce the incidence of ASD by avoiding damage to posterior structures. Posterior surgical approach is known to be one risk factor for ASD.¹⁴⁹ The ability to restore lordosis, to restore interbody height, and to correct spinal misalignment are other ALIF attributes that may offer a protective effect on the long-term adjacent level stresses.¹⁵⁰⁻¹⁵²

■ APPLICATIONS OF ANTERIOR LUMBAR INTERBODY FUSION IN REVISION SURGERY

Revision anterior lumbar surgery can present a significant challenge for the access surgeon in particular. Revision exposure of the spine requires mobilization of the peritoneal sac, which may be adherent to the anterior abdominal wall muscles. Revision exposure also requires mobilization of the major vessels and ureter, which may be encased in fibrous tissue and, thus, adherent to each other and to the anterior surface of the spine. This can present an insurmountable problem depending on the type of revision anticipated. Nguyen and colleagues¹⁵³ reported an 89% incidence of vascular complications with revisions at L4-L5 and a 40% incidence of vascular complications with revision exposure at L5-S1. Schwender and colleagues¹⁵⁴ reported that complications associated with revision anterior lumbar surgery were 3-5 times more frequent than for primary lumbar exposures in his series, specifically for venous injuries and RE.

■ INNOVATIONS RELATED TO ANTERIOR LUMBAR INTERBODY FUSION

Some early experience with robot-assisted anterior lumbar surgery has recently been published. Both Beutler¹⁵⁵ and Yang¹⁵⁶ independently performed a robotic-assisted ALIF in a porcine model, using the da Vinci Surgical System. Beutler reported that the anterior transperitoneal approach

to the lumbar spine was accomplished with enhanced visualization and dissection capability with maintenance of pneumoperitoneum using the robot. Blood loss was minimal. The visualization of the interbody space and surrounding structures was described as equivalent to or better than traditional open or other laparoscopic techniques. Yang reported that while the entirety of this first trial procedure took 6 hours, the use of the da Vinci System for ALIF was felt to be safe and effective. The use of this advanced technology may be beneficial, particularly if it can indeed reduce the risk of approach-related complications. With this goal, future development of robotic techniques for anterior lumbar spine applications is anticipated.

■ KEY POINTS

- ALIF is advantageous because of the possibility to easily and thoroughly resect the pathological disc while sparing the posterior structures.
- Stand-alone ALIF with well-designed Cage or augmentation of ALIF with anterior or posterior fixation will increase the segmental stiffness, which is supposed to promote fusion rate.
- Minimally invasive ALIF has the theoretical advantages over the common open ALIF, but it may be accompanied with long and steep learning curve and even higher rates of complications.

INTRODUCTION

First introduced in the 1940s, posterior lumbar interbody fusion (PLIF) is a common surgical technique for treating pain and/or instability of the lumbar spine. In 1943, Cloward devised a procedure for treating ruptured lumbar intervertebral discs that restored the intervertebral space while immobilizing the adjacent vertebral bodies, initially using impacted blocks of iliac crest bone then switching to cadaver bone in 1947.¹ This procedure, known as PLIF, became popular for spinal stabilization in the early 1950s after Cloward's reports of "complete long-term cures" in over 85% of patients—a "cure rate" that was 30–50% higher than that reported after simple disc removal.¹ The use of PLIF remained limited, however, due to significant technical demands and a high complication rate, including pseudarthrosis and nerve root irritation.^{2,3}

Posterior lumbar interbody fusion provides several theoretical advantages over the traditional dorsal or intertransverse (posterolateral) fusion techniques. Posterior lumbar interbody fusion enables access to the posterolateral and intervertebral disc space from a single posterior-only approach and provides increased graft load sharing because the center of fusion is proximate to the center of motion.⁴ In addition, PLIF creates a wider surface area of bone-to-graft contact⁵ and provides a rich cancellous blood supply to the graft, both of which increase the likelihood of solid fusion.⁶

The goals of PLIF are to restore and maintain intervertebral disc space height, provide sagittal and coronal correction while indirectly decompressing the nerve roots, arrest micromotion and hypertrophic degenerative disc disease (DDD), restore load-bearing capacity to anterior structures, achieve solid fusion, remove the disc that may be a source of back pain, and prevent recurrent disc herniation.^{2,3,5–10} Posterior lumbar interbody fusion is theoretically an ideal technique for the treatment of lumbar spine instability, whether congenital, acquired, or iatrogenic, because lumbar interbody fusion eliminates the instability that is a primary cause of pain. The success rate of PLIF is high, with arthrodesis rates between 77% and 100%.^{3,11–17}

MODIFICATIONS TO THE ORIGINAL SURGICAL TECHNIQUE

Over the past six decades, there have been many modifications to the original PLIF technique, with the goal of maximizing surgical ease and safety and minimizing morbidity. Although the basic surgical principle has remained the same,¹⁸ improved posterior interbody access and implant designs have resulted in shorter operating times, less neurologic injury, and improved outcomes.¹⁸ Posterior instrumentation was devised to increase fusion rates. Pedicle screw instrumentation in the 1970s allowed wider resection and wider decompression; spinal stabilization was achieved using pedicle screw-rod and pedicle screw-plate constructs.¹⁹

In 1977, Lin described a technical modification to the original PLIF technique, which involved preservation of the posterior portion of the motion segment, total discectomy to provide a larger area of bony contact between the grafts, only partial decortication of the endplates, and a functional and mechanical “unigraft” concept. Lin reported a 94% fusion rate and improved postoperative stability.^{20,21} Blume²² reported that unilateral PLIF with a bone dowel and cancellous bone chip preserved the posterior ligament structure. Branch’s modified PLIF, described in 1987, precluded the need for either banked bone or harvested iliac crest bone and, despite the removal of the posterior elements, provided posterior stability with the facet fusion.²³ Steffee and Sitkowski introduced the use of pedicle screws and plate fixation to supplement interbody fusion,²⁴ resulting in improved spinal stability,¹⁸ an increased rate of arthrodesis, and a reduced rate of graft migration.² Titanium interbody cages became prevalent in the 1980s, resolving the problems arising from autograft harvesting² and providing containment for the interbody graft. The titanium cages provided immediate spinal stability, restoration of the disc space, and an increased surface area, all of which contributed to successful fusion.²

Another modification to the original PLIF technique involved removing almost the entire facet complex. Unilateral or bilateral facetectomies became increasingly popular because they allowed the disc space to be approached in a manner limiting thecal sac and nerve root retraction, thus minimizing nerve root injury. Abumi et al. found that a unilateral facetectomy produced fewer increases in flexion and axial rotation.²⁵ Zhao et al. found that a unilateral facetectomy and hemilaminectomy enabled sufficient decompression for the placement of a single threaded interbody fusion cage while maintaining posterior supporting spinal structures.^{18,26,27} Shin et al. performed PLIF with two cages via a unilateral medial facetectomy and hemilaminectomy, which enabled sufficient decompression and solid interbody fusion while preserving most of the posterior elements.²⁸ When there is limited disc space, nerve root anomalies blocking access to the disc space, or epidural scarring, PLIF may be performed with a unilateral cage.^{5,7} Although bilateral cage PLIF is used routinely, it has a greater cost, may destroy many of the lumbar posterior elements, and may cause bilateral nerve root damage.^{5,27} Unilateral cage PLIF is less expensive because of fewer transfusion requirements, less operating time, and less blood loss,⁵ and has a lower risk of both epidural fibrosis and injury to neural structures from excessive root retraction.²⁹ For both

unilateral and bilateral cage PLIF, fixation stability, and both radiological and clinical results, were similar.⁵

Interest in PLIF was renewed in the 1990s after new interbody implants, improved graft sources, and improved instrumentation led to increased fusion rates.^{3,30-32} In 1997, Ray reported an average fusion rate of 96% using threaded cages.³³ Several years later, Chitnavis et al. and Brantigan et al. reported 95% and 98.9% fusion rates, respectively, using carbon fiber cages.^{34,35} Posterior lumbar interbody fusion has now become a widely accepted and reliable treatment option for patients with DDD, degenerative spondylolisthesis, and spinal deformity.²

PATIENT SELECTION

As with any spinal procedure, proper patient selection is critical in determining PLIF success. While there continues to be some controversy regarding surgical indications, all patients must meet indications for both lumbar decompression and lumbar fusion. There are currently no evidence-based guidelines for choosing PLIF over other posterior or anterior fusion approaches,³⁶ and the surgical indications for PLIF are continually being updated.^{36,37}

Current indications for PLIF include DDD with debilitating low back pain, severe segmental instability, spondylolisthesis, degenerative scoliosis, recurrent disc herniation, pseudarthrosis, and failed back surgery syndrome.^{3,9,13,32,36,38-40} Relative contraindications for PLIF include severe epidural fibrosis with resulting risk of nerve injury, severe osteoporosis, discitis, active infection, adhesive arachnoiditis, severe subchondral sclerosis, severe ankylosis, severe disc space collapse, and conjoined nerve roots restricting access to the disc space.^{3,9,13,32,36-39}

It is critical to ensure that potential patients have undergone several months of conservative therapy unless they present with a focal neurologic deficit. A detailed history, physical examination, and radiographic workup are important in determining the correct diagnosis. It is also important to thoroughly evaluate patients with chronic pain syndromes or psychosocial disorders, as well as those who may be seeking compensation or litigation, as it has been shown that these patients have worse outcomes following surgery.⁴¹⁻⁴⁴ Important diagnostic imaging studies include lateral flexion-extension radiographs, computed tomography (CT), CT-myelography, and/or magnetic resonance imaging (MRI) (Figs. 70.1 and 70.2). Both CT-myelography and MRI are useful in identifying central or neuroforaminal stenosis, which is commonly seen in cases of DDD and adult spinal deformity. Neuroforaminal stenosis and

Fig. 70.1: A 45-year-old man with low back pain refractory to non-surgical therapy. Sagittal T2 magnetic resonance imaging shows two-level disc disease.

associated radicular pain can be particularly difficult to alleviate without correcting the associated degenerative deformity when present.

■ OPERATIVE TECHNIQUE

The fundamental techniques of PLIF are to (1) remove the degenerated disc materials and thoroughly clean the endplates from cartilaginous layers; (2) insert the cage without damaging the bony endplates; (3) select appropriately sized cages; and (4) apply adequate compressive force with the pedicle screws to the disc space in order to stimulate fusion.²

Positioning

Open PLIF is performed with the patient placed in the prone position on a Jackson table or with chest rolls on a Wilson frame. Intra-abdominal pressure should be minimized to avoid venous engorgement, stasis, and epidural venous bleeding. The patient is prepped and draped in the standard sterile fashion.

Exposure

Intraoperative X-rays are obtained to confirm the proper level prior to making the skin incision. Once the skin incision is made, it is taken down to the lumbosacral fascia, which is opened in the midline. A subperiosteal dissection is then performed in the usual manner. It is important to

Fig. 70.2: Axial T2 magnetic resonance imaging shows bulging degenerative disc with canal compromise.

extend the dissection laterally beyond the border of the pars and articulating facet joints. In order to minimize blood loss and postoperative pain, the transverse processes do not need to be exposed, unless transverse process fusion is planned in addition to PLIF.

After radiographic verification of the correct level, interlaminar decompression is performed to achieve adequate exposure of the disc space. It is at the surgeon's discretion whether a partial or full facetectomy is performed. We prefer to remove the entire facet joint to maximize exposure for intervertebral graft placement with minimal neural retraction. Complete facetectomy is performed when transpedicular instrumentation will be used.

Depending on the amount of bone that needs to be removed for adequate decompression, either a laminotomy or full laminectomy is performed. We prefer to perform a full laminectomy and remove the spinous processes in order to keep the thecal sac under direct visualization and make retraction safer, but this is not required for interbody fusion. Gentle retraction of the nerve roots and thecal sac allows identification and proper coagulation of the epidural venous plexus over the dorsal annulus in order to maintain a dry operative field.

Discectomy

With careful nerve root retraction, a No. 15 blade is used to incise the annulus widely. Starting with a 7 mm intradiscal shaver, the disc space is entered from one side with the shaver parallel to the endplates and is then rotated

several times. Intradiscal shavers have side cutting edges, which remove both disc and the endplates. Using progressively larger shavers on alternating sides will allow for distraction of the disc space and aggressive removal of disc material bilaterally. Removing as much of the dorsal disc material as possible will provide a sufficient area of bone contact between the vertebral bodies and grafts, thus maximizing the likelihood of fusion. It is also critical to remove the cartilaginous end plates down to the level of cortical cancellous bone to ensure there is adequate blood supply for interbody fusion.⁴⁵

Fig. 70.3: Postoperative computed tomography shows placement of two polyetheretherketone cages. Note bone chips in disc space.

Grafting and Instrumentation

Once the disc space is adequately prepared, the chosen graft material is placed. Posterior lumbar interbody fusion with transpedicular instrumentation is more common than non-instrumented PLIF techniques, because instrumentation has been shown to decrease postoperative complications such as pseudarthrosis, graft displacement, and progressive kyphosis.^{46,47} Therefore, PLIF with transpedicular instrumentation will be the method discussed in this section.

Even with transpedicular instrumentation, autologous cancellous bone cannot be used as an interbody graft by itself, as it does not have the mechanical strength required to maintain the disc height. Either a corticocancellous graft or an intervertebral fusion device is required to supply sufficient vertebral column support postoperatively (Fig. 70.3). Regardless of the implant chosen, it must provide a proper fit. The dorsal portion of the graft should be shaped in a curvilinear fashion to correspond with the adjacent vertebral bodies and should be placed so that it is 5 mm ventral to the spinal canal.

Once the graft has been placed, all distracting instruments are carefully removed to allow the fusion segment to compress to help prevent bone graft extrusion. At this point, all neural elements should be checked to ensure they are fully decompressed. Interpedicular instrumentation is then performed to immobilize the spine and to provide compression loading of the bone graft between the well-vascularized vertebral bodies in order to stimulate bone fusion according to Wolff's law⁴⁸ (Figs. 70.4 to 70.8).

Fig. 70.4: Sagittal X-ray 2 years after surgery shows solid fusion with restoration of height and lordosis.

Fig. 70.8: Postoperative anteroposterior X-ray shows adequate cage placement and restoration of disc height.

COMPLICATIONS

Several types of complications can occur following initial PLIF surgery, primarily due to the challenging nature of the procedure. These complications run the gamut from mildly annoying to potentially devastating and can occur in up to 37.5% of cases.^{9,49} The overall reported complication rates of PLIF range from 8% to 80%,^{3,11,13-16,39,50-52} due to reporting variations.³

The complications commonly associated with open PLIF are intraoperative neurologic injury, interbody implant or bone graft migration, dural tear, infection, heterotopic

ossification, postoperative radiculopathy, osteolysis, and subsidence.³ Other complications associated with open PLIF are symptomatic atrial septal defect, intervertebral disc space collapse with resultant neuroforaminal stenosis, segmental instability or pseudarthrosis, increased blood loss, prolonged operating time, more extensive dissection, and a higher intraoperative complication rate.^{6,8} Postoperative infection has been reported in up to 9% of patients,^{3,11,13,39,50,52} the risk of which may be reduced by perioperative antibiotics, limited soft tissue dissection, and shortened surgical time.³ Incidental dural tears are among the most common iatrogenic injuries during open PLIF, with an incidence of 2–14%.^{3,13,15,39,50,52} Incidental durotomy increases operative time, blood loss, and length of hospital stay.^{3,53}

One of the most serious complications associated with PLIF is postoperative neurologic deficit, with incidence rates ranging from 9% to 24.6%.^{9,36,49} Postoperative neurologic complications include paresthesias, unrelenting pain, or neurologic deficit, and often occur if the exiting nerve root is over-retracted during graft placement. Radicular pain is the most commonly reported symptom of intraoperative neurologic injury.^{3,11,15,50,52} The incidence of neurologic complications can be reduced by removing more bone to facilitate graft insertion and meticulously protecting the nerve during interbody preparation and implant placement. We often place a freer or other instrument between the nerve and the graft or cage when it is tapped into the disc space.

Any posterior lumbar surgery may result in complications, and these include dural tear with or without cerebrospinal fluid leak, pedicle screw malplacement and/or breakage, wound infection requiring antibiotics and/or debridement, postoperative hematoma, prolonged pain, anesthetic problems, iliac artery injury, increased blood loss, arachnoiditis, iliac crest bone harvest site pain, delayed wound healing, intraoperative pedicle fracture, pulmonary embolism, cerebellar infarction or hemorrhage, or epidural fibrosis or scarring.^{9,21,31,36}

Additional challenges in performing PLIF are achieving solid fusion, as well as restoring disc space height and lordosis. Pseudarthrosis can occur if there is not enough appropriate graft material. The gold standard for grafting has been autologous iliac crest bone; however, the harvesting procedure has its own set of complications, including nerve injury, chronic pain, and a dearth of bone. Alternatives to iliac crest bone graft include allograft, local autograft, demineralized bone matrix, or recombinant bone morphogenetic protein (rhBMP). These materials are often morselized and placed in a cage, usually polyetheretherketone, before the graft is inserted into the disc space. We often place autograft into the disc space before cage placement to enhance the likelihood of fusion. We use lordotic spacers to restore proper disc space alignment, and distract the disc space with pedicle screws to allow for the largest possible graft to be placed. The graft is then loaded in compression. Graft or cage migration, subsidence, and disc space collapse can potentially be avoided by proper preparation of the endplates, appropriate graft size and shape, and the use of pedicle screws.

The use of rhBMP to achieve interbody fusion has increased in the past several years. Recombinant bone morphogenetic protein used in PLIF is currently off-label,⁵⁴ but has been shown to facilitate bone growth and fusion.^{3,9,14,16,17,51} The optimal dosage of BMP in PLIF remains elusive.³ In patients undergoing PLIF with BMP, complications have included radiculitis, ectopic bone formation, osteolysis, and poorer global outcomes.^{3,55} Ectopic bone formation outside the disc space and into the spinal canal may lead to possible radicular complaints.^{56,57}

MINIMALLY INVASIVE APPROACHES

In the past several years, there has been an increased interest in minimally invasive PLIF.

This procedure offers several potential advantages, including less tissue dissection, decreased surgical site infections, less postoperative pain, less blood loss, shorter

hospital stays, and earlier return to work.^{9,58-62} These advantages appear to be related to the decreased tissue dissection.³ Indications for minimally invasive PLIF are the same as for open PLIF. Overall outcomes appear to be similar to those of open PLIF,⁶²⁻⁶⁵ but further long-term data is needed. Minimally invasive PLIF can be challenging due to the smaller work space and limited visualization. Reported complications include neurologic injury, increased reoperation rate, implant migration, and pseudarthrosis.^{3,52,61,62}

In the minimally invasive approach, the patient is placed prone and fluoroscopy is used to determine the correct operative level. A short vertical incision is made in the paraspinal area. A Steinman pin and serial dilators are used to perform the muscle splitting. After appropriate muscle dissection has been performed, a tube is attached to the flexible table-mounted arm and the dilators are removed. The laminotomy and discectomy are performed through the tube in a fashion similar to an open discectomy. End-plate preparation can be performed with curettes and rasps, and then the disc space can be distracted with the trial sizers. Bone chips can then be placed in the disc space, and the interbody graft device is tapped into place. Final placement can be assessed with fluoroscopy. Fluoroscopy is also used to place percutaneous pedicle screws. The pedicles are cannulated with a needle and then tapped into place. A K wire is then placed in the pedicle, with removal of the needle. A tap can be placed over the K wire into the pedicle, and then pedicle screws are advanced into the vertebral body. Proper position is verified with anteroposterior and lateral fluoroscopy. Rods are then placed and tightened with screw caps (Figs. 70.9 to 70.11).

Fig. 70.10: Intraoperative fluoroscopy shows cage placement before tube is removed.

Fig. 70.11: Intraoperative X-ray shows placement of cage and percutaneous pedicle screws.

CONCLUSION

Careful patient selection and meticulous surgical techniques are critical to PLIF success. While PLIF continues to be a technically demanding procedure, recent improvements in surgical techniques and interbody implants have led to impressive fusion rates with excellent patient outcomes.

KEY POINTS

- Proper patient selection is critical in determining PLIF success. Current indications for PLIF include DDD with debilitating low back pain, severe segmental instability, spondylolisthesis, degenerative scoliosis, recurrent disc herniation, pseudarthrosis, and failed back surgery syndrome.
- The fundamental techniques of PLIF are to remove the degenerated disc materials and thoroughly clean the endplates from cartilaginous layers, insert the cage without damaging the bony endplates, select appropriately sized cages, and apply adequate compressive force with the pedicle screws to the disc space in order to stimulate fusion.
- Posterior lumbar interbody fusion with transpedicular instrumentation is more common than noninstrumented PLIF techniques, because instrumentation has been shown to decrease postoperative complications such as pseudarthrosis, graft displacement, and progressive kyphosis.

- Even with transpedicular instrumentation, autologous cancellous bone cannot be used as an interbody graft by itself, as it does not have the mechanical strength required to maintain the disc height. Either a corticocancellous graft or an intervertebral fusion device is required to supply sufficient vertebral column support postoperatively.
- Several types of complications can occur following initial PLIF surgery, primarily due to the challenging nature of the procedure.
- In the past several years, there has been an increased interest in minimally invasive PLIF. This procedure offers several potential advantages, including less tissue dissection, decreased surgical site infections, less postoperative pain, less blood loss, shorter hospital stays, and earlier return to work.

- » Clinical Results

INTRODUCTION

Different procedures of spinal fusion have been developed since Albee FH and Hibbs RA first reported on posterior fusion in 1911. Over the years, there have been differing opinions among surgeons as to appropriate procedures to use for various spinal etiologies. Lumbar fusion surgery is being performed with increasing frequency, particularly for the treatment of degenerative diseases. Concurrently, lumbar interbody fusion techniques have been refined, and the surgeon now has a number of treatment options with regard to instrumentation, bone graft material, and surgical approach.^{1,2}

Posterior lumbar interbody fusion (PLIF) after lumbar disc removal was first reported by Jaslow³ in 1946. The “father” of PLIF, however, was believed to be Cloward.⁴ Although PLIF requires only one surgical approach, it is associated with significant retraction on the thecal sac and nerve roots, with the attendant potential for root injury.^{1,5} Unfortunately, PLIF is also limited to the lower lumbar spine (L3-S1) owing to the risk of damage to the conus medullaris at higher levels. In 1982, Harms and Rolinger⁶ suggested the placement of bone graft and titanium mesh cage, via a transforaminal route, into disc space that previously had been distracted using pedicle screw instrumentation [transforaminal lumbar interbody fusion (TLIF)]. This approach can be accomplished without exposing more than the unilateral foramen, and retraction on the thecal sac is minimal. This approach also can be particularly advantageous in the face of scarring tissue after prior surgery.

INDICATIONS

Like PLIF, TLIF is a single-stage posterior procedure that achieve stable three-column fixation. Unlike PLIF, however, TLIF requires exposing only the unilateral neural foramen (although bilateral decompression can be performed if needed) and since a complete facetectomy is performed, less neural retraction is required which leads to a lower incidence of dural or neurologic injury.⁷ Consequently, TLIF can be performed safely above L3 with minimal risk of conus injury and is better suited for reoperations with significant epidural fibrosis because only a one-sided, lateral dural exposure is needed.^{8,9} However, one potential disadvantage of TLIF technique is that by performing a total facetectomy, the spine is significantly destabilized. Thus, posterior fixation, typically using bilateral pedicle screw, is mandated to keep the adequate stability.

Transforaminal lumbar interbody fusion is currently performed for the following conditions: low-grade spondylolisthesis, degenerative disc disease, discogenic low back pain, recurrent lumbar disc herniation associated with significant mechanical back pain, foraminal stenosis and radiculopathy, lumbar deformity, and multiply-operated lumbar spine.

SURGICAL TECHNIQUE

The patient is placed in the prone position with fully extended hip joints and legs on a four-poster frame to maintain lordosis throughout the procedure. It is important to

Fig. 71.1: Laminectomy, unilateral facetectomy, or both are performed, depending on the clinical situation. Using the distraction device across the pedicle screw construct nerve roots, thecal sac, and disc space can be easily visible.

allow the abdomen to hang free and to allow positioning for appropriate radiographs. Bilateral subperiosteal dissection is extended just lateral to the facet joints through a midline posterior approach, and the facet capsules are denuded with electrocautery.

A laminectomy, unilateral facetectomy, or both are performed, depending on the clinical situation. Minimally, a unilateral laminotomy and partial facetectomy are performed on the more symptomatic side. A complete facetectomy is not always necessary. In cases requiring more medial decompression, a medial facetectomy is sufficient for exposure. In cases not requiring medial decompression, exposure is obtained by removing the lateral aspect of the inferior articular facet to the point at which the edge of the thecal sac is visualized. Following the placement of segmental pedicle screws, distraction across the pedicle screw-rod construct is performed which allows for easy visualization of the nerve roots, thecal sac, and disc space (Fig. 71.1).

The disc is incised with a no. 15 blade and removed with a rongeur, and then the posterior lip of each endplate is removed with the use of an osteotome, while carefully protecting the thecal sac and nerve roots. This facilitates complete removal of the cartilaginous endplate and more extensive disc excision. Ringed curettes or osteotomes are used to remove disc material from the vertebral endplate. Extreme care is taken reaching across to the contralateral disc area. Harvested local bone combined with or without iliac crest autograft is packed anteriorly in the disc space.

Fig. 71.2: Harvested local bone and intervertebral cage are packed anteriorly in the disc space and directed across to the contralateral disc space.

The intervertebral cage or spacer is then placed and directed across to the contralateral disc space, and if necessary, a second spacer is then placed on the side of the approach (Fig. 71.2).

After the interbody construct is placed, the pedicle screws are attached to and compressed on the rod, thereby restoring lumbar lordosis while maintaining the restored disc height (Fig. 71.3).

Postoperatively, a custom orthosis is worn for 3 months. Patients are encouraged to walk as early as the first postoperative day.

GRAFT MATERIALS FOR INTERBODY FUSION

Following a complete discectomy, a structural spacer filled with osteoinductive graft material should be placed into the interbody space in order to maintain intervertebral body height, lumbar lordosis, and sagittal balance.

Current options for interbody spacers include titanium cages, carbon fiber cages, polyetheretherketone cages or absorbable cages.

CLINICAL RESULTS

The goals of TLIF are to relieve pain and neural compression in conjunction with achieving a stable arthrodesis. From a biomechanical perspective, TLIF offers all of the same expected benefits of PLIF. Biomechanical analysis

Fig. 71.3: Postoperative X-ray.

has demonstrated that >30% of the vertebral endplate surface area is required to achieve rigid interbody fusion,¹⁰ and in vivo clinical study has demonstrated that 69% disc volume excision (56% of endplate surface area) can be achieved through a unilateral transforaminal approach.¹¹ Thus, TLIF can provide adequate surface area for solid interbody fusion.

There are many evidences supporting the efficacy of the TLIF technique. Potter et al. prospectively analyzed 100 consecutive patients with degenerative lumbar disease treated with TLIF with bilateral pedicle screw fixation. They concluded that TLIF is a safe and effective method of achieving lumbar fusion with a 93% radiographic fusion success and a nearly 80% rate of overall patient satisfaction, but frequently results in incomplete relief of symptoms.¹² Yan et al. compared the therapeutic effect of PLIF and TLIF with pedicle screw fixation on treatment with 187 patients with degenerative spondylolisthesis, and concluded that interbody fusion with either a PLIF or a TLIF technique provides equivalent pain relief or functional outcomes in the treatment of degenerative spondylolisthesis.¹³

Tormenti et al. analyzed perioperative complication rates of 531 TLIF procedures at a large academic medical center using institution's complication database or the medical record.¹⁴ One hundred thirty-five patients (25.4%) had at least one procedure-related complication. The most common complications were durotomy (14.3% of patients) and infection (3.8% of patients). The overall complication rate was greater in those patients who had undergone a previous operation (OR 1.75, 95% CI 1.18–2.59; $P < 0.01$) and in those who had multilevel surgery (OR 1.54, 95% CI 1.04–2.28; $P = 0.03$). Moreover, Khan et al. reported

perioperative complications in patients undergoing TLIF as a revision surgery.¹⁵ They concluded, in the hands of experienced surgeon, that revision open TLIF does not necessarily increase the risk of perioperative complications compared with primary TLIF. Two or more previous lumbar decompressive procedures, however, increase the risk of inadvertent dural tears and neural injury.

Minimally invasive techniques for TLIF (MIS TLIF) have recently been introduced with the aim of smaller wounds, less tissue trauma, and faster recovery. Lee et al. performed prospective cohort study to compare the clinical and radiological outcomes of single-level open versus MIS TLIF.¹⁶ One hundred forty-four single-level open and MIS TLIF were performed with 72 patients in each group. At 6 months and 2 years, clinical outcome analysis showed both groups improving similarly in terms of visual analog scale (VAS), Oswestry disability index (ODI), short form 36-item health survey (SF-36), return to full function, and patient rating. However, MIS patients have less intraoperative blood loss, needed less morphine, and were able to be discharged from hospital earlier ($P < 0.05$). Therefore, the MIS TLIF provides similar clinical and radiological outcomes with additional benefits of less perioperative blood loss and pain, and a shorter hospital stay.

SUMMARY

Transforaminal lumbar interbody fusion can be performed with acceptable risk and will result in a satisfactory outcome using a single posterior approach. Complications are generally minor and transient in nature. In spite of this, patients may have residual symptoms postoperatively, indicating a need for detailed preoperative evaluation and rigorous patient selection.

KEY POINTS

- Transforaminal lumbar interbody fusion is a single-stage posterior procedure that achieve stable three-column fixation.
- Transforaminal lumbar interbody fusion exposes only the unilateral neural foramen; since a complete facetectomy is performed, less neural retraction is required, thereby leading to a lower incidence of dural or neurologic injury. Consequently, TLIF can be performed safely above L3 with minimal risk of conus injury and is better suited for reoperations because only a one-sided, lateral dural exposure is needed.

- In vivo clinical study has demonstrated that 69% disc volume excision (56% of endplate surface area) can be achieved through a unilateral transforaminal approach.
- Interbody fusion with either a TLIF technique or a PLIF technique provides equivalent pain relief or functional outcomes in the treatment of degenerative disease.
- Transforaminal lumbar interbody fusion can be performed with acceptable risk and will result in a satisfactory outcome using a single posterior approach. Complications are generally minor and transient in nature.

INTRODUCTION

Normal aging results in decreased proteoglycan content of the disc nucleus resulting in a drop in nucleus pressure. When there is disc degeneration, there is also structural damage to disc matrix and increased activity of the matrix degrading enzymes. These changes lead to loss of disc height and bulging of the annulus radially, creating a slack of the collagen fibers of the outer annulus and intervertebral ligaments—overall resulting in segmental instability. The natural response to this increased mobility and radial bulging of the disc is the formation of vertebral body osteophytes that reconstitutes segmental stability by limiting bending motion (Adams, 2006, Spine). When these osteophytes are formed on the posterolateral aspect of the vertebral body, they can encroach on the foramen in association with the bulging disc resulting in foraminal stenosis. As disc degeneration and height loss progress, there is also a shift in the compressive load bearing from the vertebral body to the posterior arch. Normally, only 25% of the load is transferred through the posterior column; however, with progressive disc degeneration, this increases up to 50% (Robson-Brown). The stress concentration in the facet joints results in cartilage loss and osteoarthritis of the posterior elements. Osteophytes arising from the facet joints would also contribute to the foraminal/lateral recess stenosis. As the disc decreases in height, it would also result in up-down stenosis at the foramen between the pedicles. In addition, ligamentum

flavum will buckle into the spinal canal resulting in central stenosis and neurogenic claudication. As the osteoarthritis of the facet joints progresses, their ability to withstand shear forces would decrease and spondylolisthesis may develop. Increased load-bearing by the posterior elements would result in stress shielding of the anterior aspect of the vertebral bodies, ultimately decreasing bone density in this region and leading to potential fractures when load is transferred back to the anterior column (Adams, 2006). Facet joints often show left-right asymmetries that can lead to abnormal axial rotation and lateral bending movements resulting in degenerative scoliosis. Asymmetric vertebral compression fractures can also contribute to the deformity. In summary, degenerative disc disease can result in a variety of clinical scenarios ranging from radiculopathy to degenerative scoliosis with sagittal and coronal imbalance. Understanding the underlying pathophysiological processes would enable one to select treatment strategies that would be able to correct the resulting deformities and decompress the neural structures in a much efficient manner.

The conservative treatment options range from medical management, physical therapy to epidural/transforaminal steroid injections, and should be exhausted first. The surgical interventions for these degenerative disorders aim to correct the deformity, decompress the neural elements, and, finally, stabilize the spine through arthrodesis (Tanaka). These goals can be achieved through all anterior, all posterior, or often combined approaches.

Posterior approaches have been the workhorse of lumbar spine surgery. It is familiar to spine surgeons, allows direct decompression of the canal by excising the redundant ligamentum flavum and foramen by undercutting of the facet joints, and achieves arthrodesis via laying bone graft between the transverse processes. However, in the setting of severe loss of disc height, up-down stenosis at the foramen cannot be addressed unless the disc height is restored through an interbody fusion. Addressing anterior column has two important implications. First, it would allow restoration of the lost disc space height that would cause decompression of the foramina and decompression of the spinal canal by tensioning and eliminating the buckling of the ligamentum flavum. Second, it will increase the rate of successful arthrodesis as anterior interbody fusion has better vascularity and increased surface area for fusion. Interbody fusion can be achieved via direct anterior lumbar interbody fusion (ALIF) or lateral lumbar interbody fusion (LLIF) methods or indirect posterior or transforaminal lumbar interbody fusion (TLIF) methods. In treatment of adult degenerative scoliosis, the posterior approaches are again more familiar to the spine surgeon; however, deformity correction and indirect decompression of the neural elements are inferior to anterior approaches. The interbody devices are smaller in size and engage the center of the endplate with a higher risk of subsidence and loss of correction. Besides, preparation of the disc space and insertion of the interbody device require extensive nerve and dural manipulation, which may lead to neurologic deficits and dural tears. Removal of the lamina and partial/complete facetectomies essentially leave only the transverse processes to achieve arthrodesis that is traditionally associated with lower fusion rates. On the other hand, anterior approaches give significant advantages to the surgeon by restoration of the disc height resulting in indirect decompression of the foramen, by addressing up and down stenosis, and canal, by stretching the buckled ligamentum flavum (Lund). In addition, lengthening the anterior column easily treats the sagittal plane deformity. The big surface area between the endplates provides an excellent environment to achieve arthrodesis. However, anterior approaches also have disadvantages such as requiring an approach surgeon in the United States, excessive dissection, and potential intraabdominal as well as abdominal wall morbidity (Bridwell). Ileus is a common postsurgical issue, with bowel injury a real possibility. Vascular injuries are rare, but sometimes life-threatening. When addressing L5-S1, injury to the superior

hypogastric plexus may lead to retrograde ejaculation that may cause significant morbidity, especially in the younger male patients. Finally, combined procedures allow best of both worlds as anterior procedures allow restoration of disc height, deformity correction, and solid arthrodesis; on the other hand, posterior procedures allow more directed decompression and additional stability to maintain correction and prevent subsidence. However, combined approaches expose patients to surgical procedures, further increasing the risk of complications. Therefore, there was an obvious need for less invasive techniques that would enable the surgeon accomplish the same result with fewer complications.

■ EVOLUTION OF LATERAL LUMBAR INTERBODY FUSION

In order to address the concerns of the conventional anterior approach while still achieving the benefits of full anterior column utilization, Pimenta presented the lateral transpsoas approach in 2001 (Ozgur). This technique eliminates the need to mobilize the vessels and, furthermore, eliminates the need for the approach surgeon. It is a true anterior retroperitoneal approach to the lumbar spine from L1 to L5 through the psoas muscle. At higher levels, it allows access up to T5 via a retropleural or transthoracic approach. This direct access to the anterior column still allows the ability to perform an extensive discectomy, particularly releasing the main deforming forces by releasing the annulus on the lateral aspect of the disc. This method has two key technical features that separate it from the conventional ALIF. First, it preserves the anterior longitudinal ligament that allows deformity correction via ligamentotaxis and stability as the interbody cage is kept in place by the tightened anterior longitudinal ligament (ALL) and posterior longitudinal ligament (PLL). Second, as the interbody cage is inserted via a lateral approach, it can span the ring apophysis with a larger footprint cage, both decreasing the risk of subsidence and increasing the potential for successful fusion. The minimally invasive nature of this approach would also allow decreased operative times and blood loss.

Complications associated with the lateral transpsoas approaches may be categorized as neural, visceral, and vascular. This approach requires placement of a retractor through the psoas muscle, where the lumbosacral plexus lies. These nerves run within and around the psoas and are not easily visible. Therefore, they are indirectly monitored and protected through a special neuromonitoring sys-

tem that provides real-time feedback on their position in the field. Hence, knowledge of the anatomy of these structures including the genitofemoral nerve is vital to avoiding their injury. Moro et al. studied the configuration and noted that above L4-L5, these nerves were at the posterior quarter of the vertebral body. At L4-L5, they cross more anteriorly into the middle-posterior quarter of the vertebral body. This translation may be further increased in the setting of spondylolisthesis, where translating cephalic segment would move the plexus more anteriorly. In addition, anatomic anomalies are seen in up to 20% of patients (Samudrala). The genitofemoral nerve has the most variations in its path as it courses in a tangential manner piercing the psoas near L3-L4. Genitofemoral injury has been reported, with patients experiencing transient post-op groin pain (Bergey). With such possible variability in the course of these nerves, there is a real possibility of complications. The most common side effect following a transpsoas approach is transient hip flexor weakness (up to 27.5%) (Tohmeh), which is believed to be a consequence of trauma to the psoas muscle itself, rather than a neural injury. Distal motor deficits (e.g. quadriceps weakness) have been reported at an incidence of 0.7–3% (Rodgers, Tohmeh). Avoidance is based on meticulous dissection along with proper neuromonitoring using free-run and triggered electromyography (EMG) (Tohmeh, Uribe).

By limiting mobilization of the peritoneal contents and vascular structures, risk of visceral and vascular injury is significantly reduced compared with a direct anterior approach. However, the risk is nonzero; the vessels continue to lie close to the surgical field; and there are reports of bowel injury (Tormenti) in the literature, but incidence over the larger population is uncertain.

■ INDICATIONS

Indications for LLIF are similar to those of any interbody fusion between L1 and L5 and include but are not limited to degenerative disc disease, instability patterns, such as spondylolisthesis (Grade I/II) and postlaminectomy, degenerative scoliosis, recurrent disc herniations, posterior pseudarthrosis, anterior column support, and adjacent segment degeneration. The latter, in particular, is ideal for standalone techniques, which will be discussed below. The lateral approach is particularly useful for revision anterior procedures such as that for failed ALIF and total disc arthroplasty, where scar tissue in the surgical plane may prohibit a secondary anterior retroperitoneal

approach. Historically, this would require a transperitoneal approach with increased risk of complication. In these instances, the transpsoas approach avoids the scarred-in plane allowing direct access.

Similarly, limitations for this approach reflect those of any interbody fusion surgery, such as infection. Limitations specific to this procedure would be approaching the L5-S1 disc space as this is not reproducibly accessible due to the iliac crest. High-grade spondylolisthesis, notably at L4-L5, can be challenging secondary to migration of the lumbar plexus anterior with the deformity. Obesity is not as challenging as it may be in ALIF, due to the lateral decubitus positioning of the patient, which allows the abdominal contents and fat to fall forward out of the surgical field.

■ PREOPERATIVE WORKUP

After a detailed history has been obtained, a thorough physical examination should be performed. The radiographic work-up should be the next step and below are a few specifics to the utilization of LLIF.

Standing radiographs are always important for the evaluation of disc height. While magnetic resonance imaging (MRI) is excellent for visualizing the disc and stenosis, it is often done while recumbent and, thus, overestimates the intervertebral disc height. The true height is best seen on radiographs and is critical in evaluating the need for height restoration in the anterior column.

Computed tomography (CT) myelography can be used in place of MRI in cases where patients have had prior surgery with metal implants. Furthermore, it can better detail the sclerosis of the endplates, an important quality in the evaluation of possible standalone constructs. If there are concerns related to bone density in these patients, dual-energy X-ray absorptiometry (DEXA) may be warranted as well.

The information obtained from these diagnostic images can be related to the previously discussed history and physical examination to obtain the diagnosis. With this the treatment plan is set following the indications for the LLIF as described above.

■ LATERAL LUMBAR INTERBODY FUSION TECHNIQUE

The keys to performing LLIF successfully and with minimal complications include careful patient selection, proper positioning, and meticulous surgical technique. Patients are positioned in the lateral decubitus position; an axillary roll is used to minimize the risk of axillary nerve neuropraxia.

To prevent lumbosacral plexus injury, intraoperative monitoring is used. Fluoroscopy is mandatory for real-time spine viewing. Clear anteroposterior (AP) and lateral projections of the lumbar spine must be obtained before the procedure can be performed. The disc space of interest is marked on the lateral fluoroscopy view. It is important at all times to maintain the fluoroscope at 90° to the patient, while also rotating or tilting the table to obtain a true lateral view of the disc. This helps to maintain a straight

Fig. 72.1: The guidance of the first dilator on to the psoas in the retroperitoneal space through a second posterior incision.

up-down orientation and lateral trajectory of all instruments being passed in and out of the disc. Failure to maintain a strict up-down orientation can result in serious vascular or neurologic injuries caused by inappropriate trajectory. For the direct lateral incision, one may use an oblique incision running parallel to the fibers of the external abdominal oblique musculature. A second posterior incision is used lateral to the border of the erector spinae musculature to introduce a finger bluntly into the retroperitoneal space, open the space, and guide the initial dilators safely to the surface of the psoas muscle (Fig. 72.1). The dilator is advanced through the psoas muscle using dynamically triggered EMG to identify the direction and proximity of spinal nerves relative to the distal end of the dilator. Once it is safely advanced through the psoas muscle, its location is confirmed with lateral fluoroscopy before the placement of a K-wire into the disc space (Figs. 72.2A and B). Subsequent dilators are advanced over the first to separate muscle fibers and widen the exposure, each using dynamically triggered EMG. Then the retractor is placed, and a lateral fluoroscopic image is obtained to ensure that the retractor is in the proper AP location. It is critical that the working zone is not too anterior; it should lie between the posterior and middle-thirds of the lateral disc space projection. The retractor is opened minimally, and a triggered EMG probe is used to stimulate the area to identify any traversing neural elements. If a nerve is seen in the field, it may be gently moved using a Penfield dissector to position it posteriorly behind the retractor. The retractor can be widened independently in the AP and cranial-caudal direc-

Figs. 72.2A and B: The first dilator should be docked on the posterior half of the targeted disc space on the lateral view (A) and flush with the disc on the AP view (B).

Fig. 72.3: The Cobb is advanced over the endplate on the AP view to the contralateral annulus that is then released by rotating the Cobb.

Fig. 72.4: Trials are inserted into the disc space to determine the ideal cage size (width, depth and height).

tions, and care should be taken to expose only as necessary to minimize trauma to the psoas muscle. Once expanded, the location of the anterior vertebral body should be defined by identifying the anterior fiber of the anterior longitudinal ligament. This will help minimize the risks of vascular injury and of anterior graft placement and dislodgment. It is important to continue to reassess the location of the anterior longitudinal ligament during the discectomy procedure.

The discectomy is performed using an annular release (Fig. 72.3). Controlled passing of a Cobb elevator is performed across the disc space beyond the contralateral annulus under fluoroscopic guidance. This is done by gently tapping the Cobb across the disc space under fluoroscopic observation. The Cobb is then rotated after it passes through the opposite annulus. In this manner, the contralateral endplate attachment is released. This allows elevation of disc height and attempts deformity correction.

Meticulous care must be taken to avoid endplate violation. Fluoroscopy should be used when spinal instruments, such as curettes, rasps, and Cobb elevators are passed into the disc space. Trials are then introduced serially into the disc space, with care taken not to oversize the graft (Fig. 72.4). A long implant that takes advantage of the biomechanical strength of the dense ring apophysis is recommended. Autologous iliac crest bone graft, or a bone graft replacement, may be placed within the spacer before it is implanted into the disc space. An understanding of the anatomy, vigilant monitoring of the surrounding neurologic structures, a meticulous and thorough discectomy, and appropriate implant placement may minimize complications.

Kepler et al. performed a CT study and demonstrated that LLIF resulted in a 64% increase in the foraminal height and 35% increase in the foraminal area. This is a much better improvement when compared with TLIF/PLIF, where a maximum 30% foraminal height restoration was achieved (Groth).

Treatment of Specific Spinal Conditions

1. *Degenerative disc disease and low-grade spondylolisthesis* (Fig. 72.5): As it was discussed in the previous section, degenerative disc disease and spondylolisthesis are common causes of back pain as well as radicular pain. The classical approach to treat these pathologies has been posterior approaches with pedicle screw fixation. Decompression of the neural elements depends on the removal of ligamentum flavum and osteophytes, and indirect decompression via TLIF/PLIF procedures which is associated with manipulation of the neural elements—all of which potentially increases the risk of injury. Lateral lumbar interbody fusion, on the other hand, allows indirect decompression of the foramen as well as canal, decreasing the need for posterior decompression. Decreasing the need for posterior exposure avoids denervation of the multifidus muscle which is an important factor in the development of adjacent segment disease. Lateral lumbar interbody fusion has also been successfully applied to lumbar spondylolisthesis. Of note, it is indicated only in the low-grade spondylolisthesis, since the risk of injury to the lumbar plexus is significantly higher in the patients with

Figs. 72.5A to D: A 37-year-old man presented with back and leg pain. The radiographic work-up revealed L4-L5 spondylolisthesis (A and B). After failure of nonoperative treatment, he underwent an L4-L5 LLIF, augmented with posterior fixation (C and D)

high-grade (Grades III and IV) spondylolisthesis. First, as the slip gets worse, the overlapping endplate area to place the cage decreases in parallel. Second, the lumbar plexus gradually moves anterior at the lower lumbar levels normally, and, in spondylolisthesis, will be further displaced where it would be difficult to find a safe zone to perform the procedure. Although the same risk still exists with low-grade spondylolisthesis, the reported lumbar plexus injury rate is comparable to degenerative pathologies without an associated slip. Rodgers et al. reported 63 patients with Grade II spondylolisthesis at the L4-L5 level without any neural injuries and all patients went onto union. Marchi et al. reported 52 patients with Grades I and II

spondylolisthesis with majority of the procedures performed at L3-L4 and L4-L5. In 20% of the patients, they reported thigh numbness and/or psoas weakness that was temporary. They did not use any additional instrumentation to support the cage and observed a union rate of 87% and subsidence rate of 17% (Marchi).

Case example: A 37-year-old man presented with back and leg pain. X-rays were taken noting L4-L5 spondylolisthesis (Figs. 72.5A and B). After failure of nonoperative treatment, he underwent an L4-L5 LLIF, augmented with posterior fixation (Figs. 72.5C and D).

2. *Adjacent segment disease following previous lumbar fusion* (Fig. 72.6): Adjacent segment degeneration following lumbar surgery may be observed in up to 35% of the patients (Klopfenstein). The most commonly utilized approach to address this problem is repeat posterior procedures. However, this approach is technically more difficult and associated with higher blood loss, increased risk of infection, dural tear, and pseudarthroses. Lateral lumbar interbody fusion is an attractive alternative in these cases, as the pathology can be addressed directly through a separate approach in a virgin territory. Lateral lumbar interbody fusion will allow restoration of the height of the collapsed/slipped disc, providing indirect decompression of the neural foramen. It can be accompanied with anterior instrumentation to increase the chance of fusion and decrease the risk of subsidence. Klopfenstein et al. reported 14 patients, where they used LLIF to treat a variety of pathologies, such as spondylolisthesis, post-laminectomy instability, and adjacent segment disease. All patients achieved union and 71% had improved radicular symptoms (Klopfenstein).

Case example: After a previous L3-S1 spinal fusion, a 75-year-old woman presented with back and leg pain secondary to adjacent level degenerative disease (Figs. 72.6A and B). She underwent standalone LLIF at L2-L3 (Figs. 72.6C and D).

3. *Standalone constructs—multilevel degenerative disc disease and degenerative scoliosis* (Fig. 72.7): Standalone LLIF application is becoming more widely utilized. It is most often discussed in the treatment of adjacent segment degeneration but is finding promise in most degenerative conditions (Marchi). The main advantage is the elimination of supplemental fixation that would decrease the surgical time and, in return, retraction time, potentially decreasing the risk of injury to the lumbar plexus. Cappuccino et al. demonstrated that when a

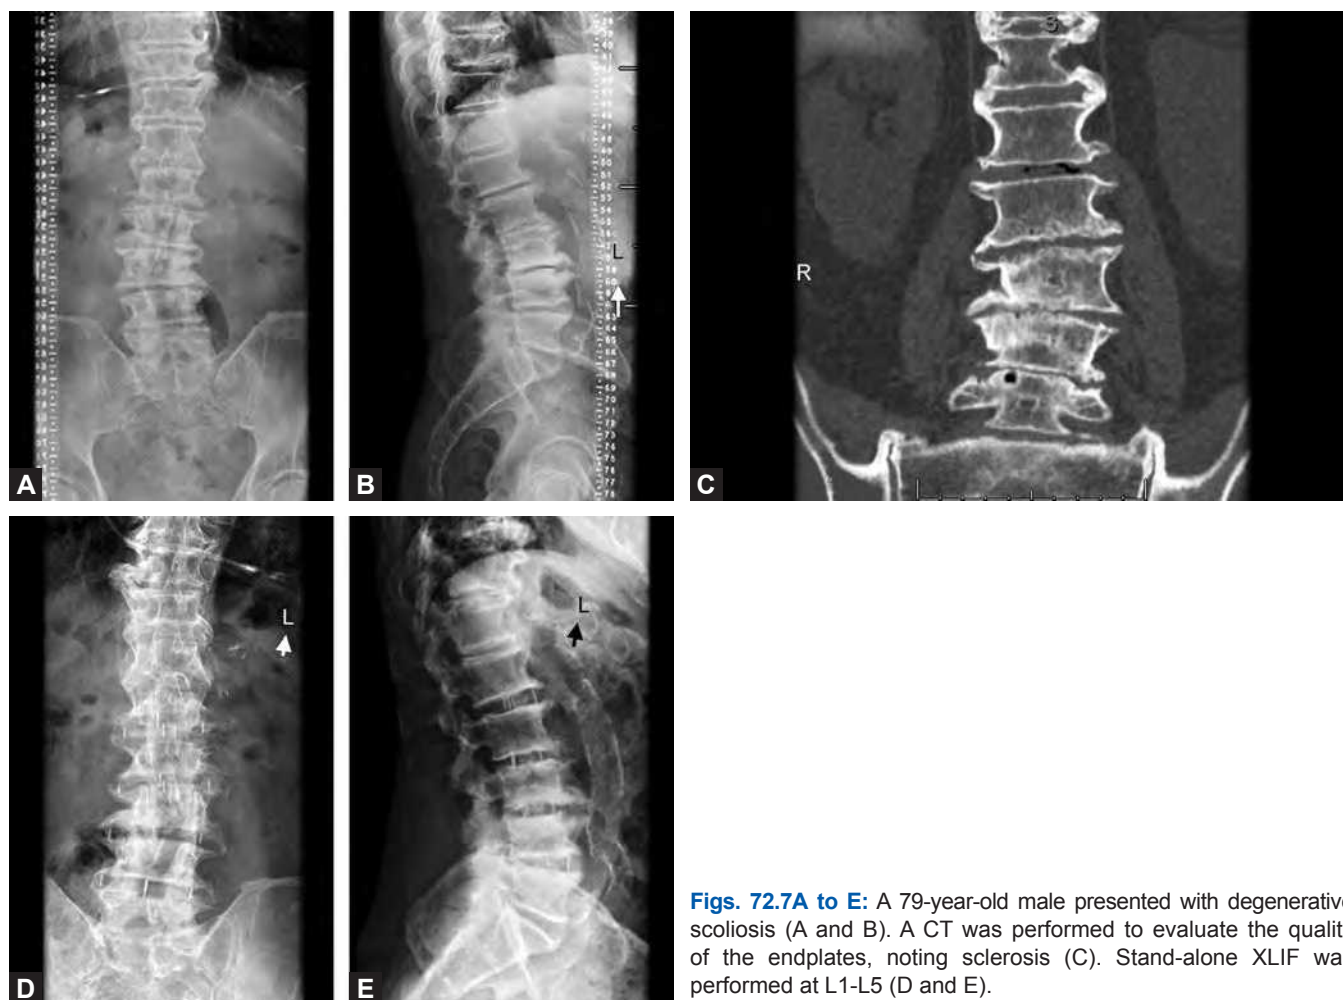

Figs. 72.6A to D: Following a previous L3-S1 spinal fusion, a 75-year-old woman developed adjacent level degenerative disease, presenting with back and leg pain (A and B). She underwent standalone LLIF at L2-L3 (C and D).

cage with big footprint is used and once it has a snug fit between the tensioned ALL and PLL, there has been a 70% decrease in the flexion-extension and lateral bending motion at the instrumented site. Addition of a lateral plate or a pedicle screw decreased the motion for an additional 10–15% (Cappuccino). It is assumed that as the degenerative cascade progresses, the arthritic changes in the facet joints will limit the ROM at the affected segment further. When combined with the anterior cage, the treated segment will hypothetically have adequate rigidity to achieve fusion. Marchi et al. reported 87% union rate with this technique. However, there was a 17% rate of high-grade subsidence, half of which required additional procedures to achieve a rigid fixation (Marchi). First and foremost, surgical technique is key to decrease the risk of this complication. Preservation of the endplates is critical, as is proper preparation to utilize the correct size of implant, maximizing biomechanical spread of force. Also, preoperative evaluation can possibly predict this. The use of DEXA scan will give insight into overall bone quality. Computed tomography scan is routinely obtained to evaluate the endplates themselves. The ideal patient for standalone cases is the patient with advanced facet arthritis, endplate sclerosis, and minimal motion on bending X-rays.

Case example: A 79-year-old man presented with back and bilateral leg pain. X-rays showed degenerative scoliosis (Figs. 72.7A and B). Computed tomography was completed to evaluate endplate, noting sclerosis

(Fig. 72.7C). Stand-alone extreme lateral interbody fusions were performed at L1-L5 (Figs. 72.7D and E). One year after surgery, the patient has continued resolution of symptoms.

4. **Complex deformity and degenerative scoliosis** (Fig. 72.8): The LLIF procedure for treating complex deformity and degenerative scoliosis may offer various clinical advantages over more traditional techniques as noted above. The LLIF procedure straightens and derotates the spine through bilateral annular release, placement of a large implant across the disc space spanning the ring apophysis, and the effects of ligamentotaxis. Segmental interbody implant placement realigns the endplates to a horizontal position, restores disc and foraminal heights, and indirectly decompresses the neural elements. Sagittal balance is also corrected and maintained by placement of an implant, either lordotic or nonlordotic, in the anterior of the disc space. Keshavarzi et al. demonstrated that the majority of the correction in both the coronal and sagittal plane was achieved during the initial LLIF procedure. In addition, the interbody space provides a superior environment for fusion compared with the posterolateral gutter used for posterior approaches. It is frequently used as the first stage of a combined approach. Staging the second posterior approach a couple of days after the LLIF would allow re-evaluating the patients to see if they need posterior decompression. Often, indirect decompression that was provided by the LLIF may eliminate the need to perform additional posterior decompression.

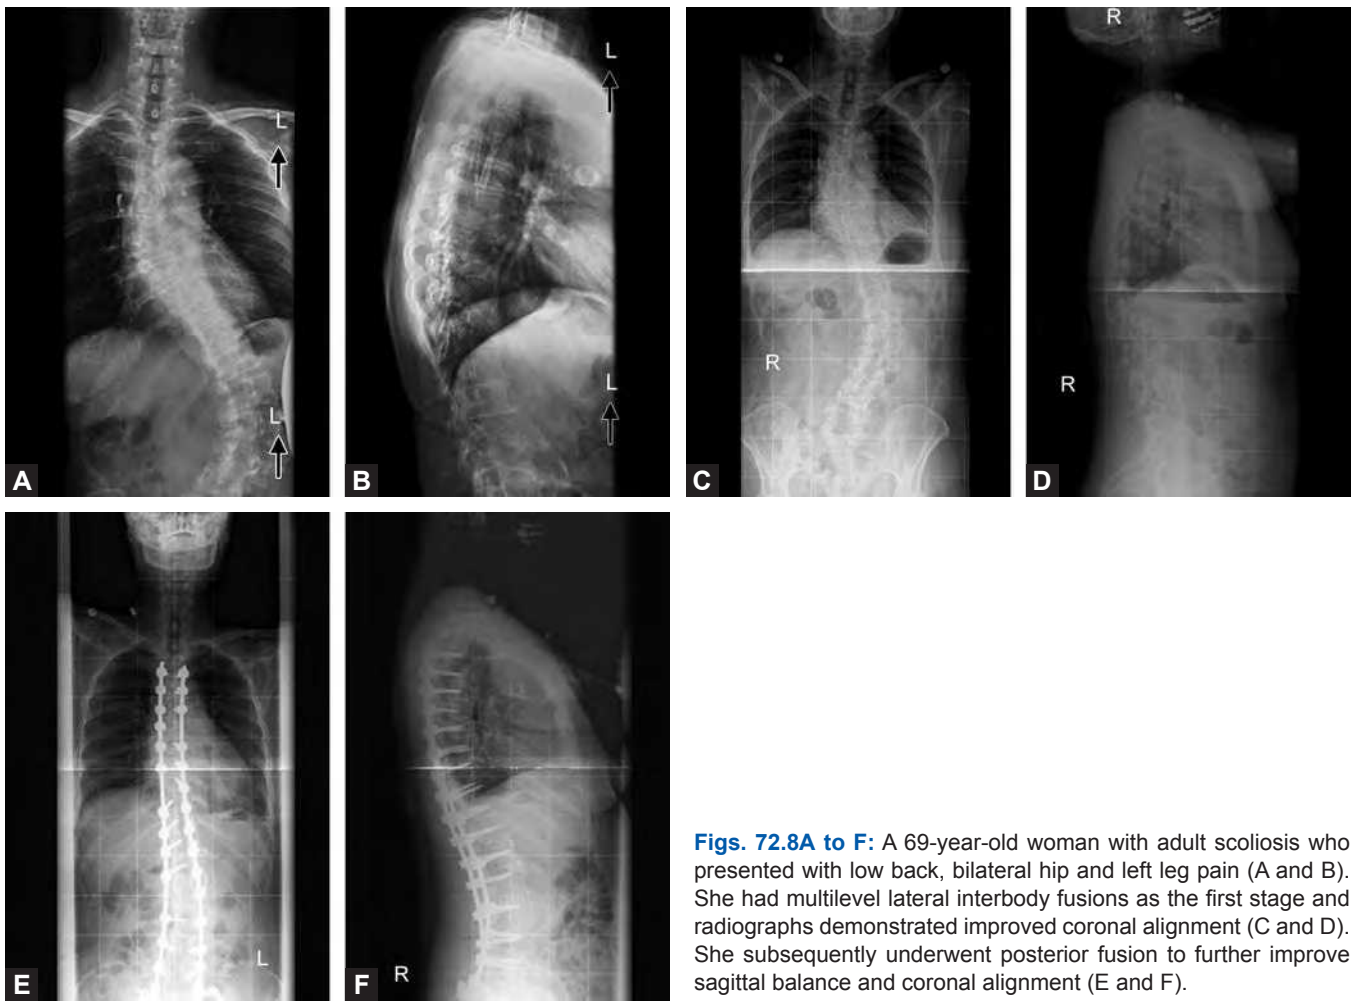

Figs. 72.7A to E: A 79-year-old male presented with degenerative scoliosis (A and B). A CT was performed to evaluate the quality of the endplates, noting sclerosis (C). Stand-alone XLIF was performed at L1-L5 (D and E).

Deciding which side to approach the spine is a critical step in the preoperative planning. Surgical approach from the concavity of the scoliosis is beneficial because it provides access to multiple levels through a single skin incision. The fractional curve at the lumbosacral junction will place the L4-L5 disc in convex side of the fractional curve, but concave side of the main curve. This will provide a reliable approach to L4-L5 where the iliac crest typically can obstruct access from the convex side of the main curve. On the convex side of the curve, the lumbar plexus will already be draped over the curve and under tension. Further traction by the retractors during the procedure would place the lumbar plexus at higher risk for injury. However, on the concave side of the curve, the lumbar plexus will be relaxed; theoretically, the risk of injury to the lumbar plexus will be less. In addition, the soft tissues and bridging osteophytes will be more prominent

on the concave side, and direct release of these structures will allow better curve correction, restoration of foraminal height, and indirect neural decompression.

Despite the advantages of the LLIF technique, there may be scenarios of severe sagittal imbalance where anterior release via LLIF may not sufficiently address the patient's deformity. In such situations, the patient may require aggressive posterior osteotomy techniques; however, even then LLIF would have an adjunctive role to decrease the pseudarthrosis rates by providing interbody fusion. The best example would be while planning a pedicle subtraction osteotomy in a patient with *de novo* scoliosis where there is no previous anterior interbody fusion. Side bending radiographs should be carefully scrutinized for flexibility of the curve. In the presence of a rigid fractional curve, correction of the main curve may lead to coronal decompensation following the LLIF procedure. This

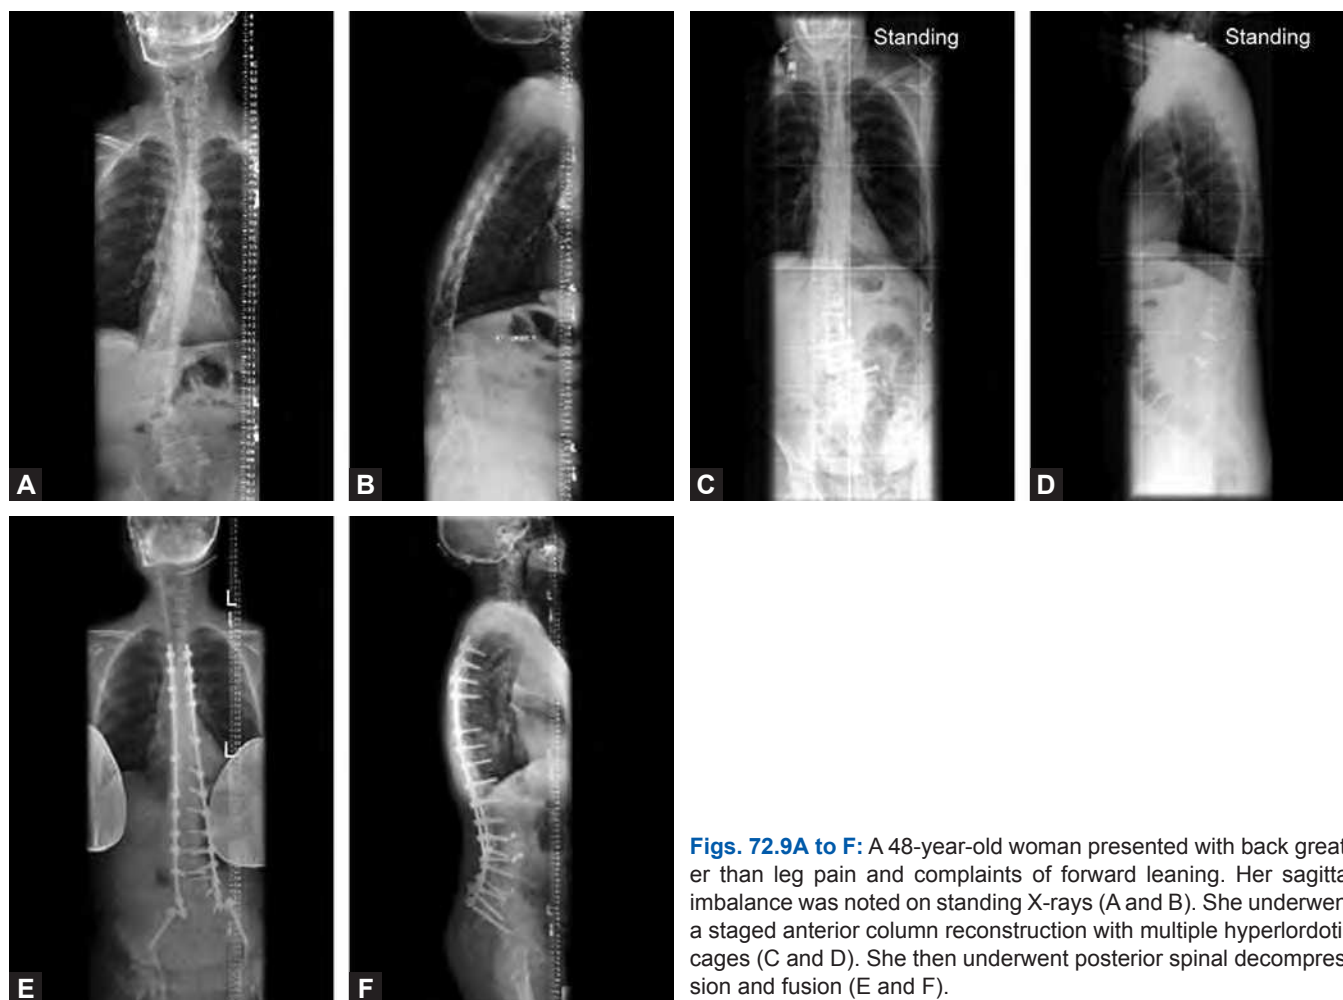

Figs. 72.8A to F: A 69-year-old woman with adult scoliosis who presented with low back, bilateral hip and left leg pain (A and B). She had multilevel lateral interbody fusions as the first stage and radiographs demonstrated improved coronal alignment (C and D). She subsequently underwent posterior fusion to further improve sagittal balance and coronal alignment (E and F).

can be addressed during the posterior procedure; however, awareness of this potential complication is important and should be discussed with the patient before the procedure (Keshavarzi). Finally, it is not uncommon for complex deformity procedures to include L5-S1 as part of the construct. In such cases, the best treatment solution for L5-S1 is often to perform the interbody treatment during supplemental posterior fixation via either ALIF or TLIF.

Case example: A 69-year-old woman presented with low back, bilateral hip, and left leg pain. Pre-operative radiographs showed decompensating away from the convexity of her structural lumbar curve in the coronal plane (Figs. 72.8A and B). After treating the anterior column, the patient experienced immediate reductions in pain and radiographs demonstrated improved coronal alignment (Figs. 72.8C and D). Two days after the anterior portion of the procedure, the

patient underwent posterior fusion to further improve sagittal balance and coronal alignment (Figs. 72.8E and F). One year after the surgery, the patient is able to walk numerous blocks and has increased her lifting abilities to meet her needs for daily living.

5. **Anterior column release to correct severe sagittal plane deformity** (Fig. 72.9): In rigid and acute sagittal plane deformities, a new modification/application of lateral interbody fusion technique is the anterior column release (ACR). This technique involves release of the ALL and anterior annulus in addition to the discectomy. A special interbody cage with up to 30° of lordosis is inserted into the disc space. This technique is frequently combined with a posterior Smith-Petersen osteotomy. Akbarnia et al. reported 28° of correction with the ACR and an additional 7° with posterior osteotomy reaching a total correction of 35°. This is

Figs. 72.9A to F: A 48-year-old woman presented with back greater than leg pain and complaints of forward leaning. Her sagittal imbalance was noted on standing X-rays (A and B). She underwent a staged anterior column reconstruction with multiple hyperlordotic cages (C and D). She then underwent posterior spinal decompression and fusion (E and F).

comparable to the correction achieved with a pedicle subtraction osteotomy, with the advantage of less morbidity to the patient, as the anterior part of the procedure is a separate stage with minimal morbidity. The preliminary results in 17 patients are promising; however, careful case selection is essential. The ideal patient would have an acute kyphotic deformity at the disc level without posterior instrumentation spanning the target segment.

Case example: A 48-year-old woman presents with back greater than leg pain and complaints of forward leaning. Her sagittal imbalance was noted on standing X-rays (Figs. 72.9A and B). She underwent a staged anterior column reconstruction with 100° total of hyperlordotic cages (Figs. 72.9C and D). Two days later, she then underwent posterior spinal fusion with decompression (Figs. 72.9E and F).

CONCLUSION

The use of the LLIF has many applications. It is a useful alternative to the traditional interbody fusion techniques, with expanded indications in standalone constructs and thoracic disc herniation. While there are limitations to its use and inherent risk, with meticulous technique, it is both easily reproducible and safe.

KEY POINTS

- Lateral interbody fusion allows excellent coronal and sagittal plane correction in addition to indirect central and foraminal decompression, making it an important alternative to classic interbody fusion techniques.
- Lateral interbody fusion cages rest on the strongest part of the vertebral endplate decreasing the risk of subsidence significantly.

- Most common complication is neuropraxia; therefore, adherence to meticulous surgical technique and a thorough understanding of the regional neurovascular anatomy is essential.
- A computed tomography scan would be helpful to evaluate endplate sclerosis when considering stand-alone constructs.
- It can be safely utilized in degenerative disc disease and low grade (I&II) spondylolisthesis patients.
- Adjacent segment disease is an excellent indication as it can be performed through a separate approach in a virgin territory.
- Stand-alone constructs should only be utilized in select patients who have advanced facet arthritis, endplate sclerosis and minimal motion on bending X-rays.
- It is a minimal invasive means of achieving coronal and sagittal plane correction in adult spinal deformity patients, and frequently utilized in combination with posterior approaches.
- Anterior Column Realignment is a powerful minimally invasive alternative to pedicle subtraction osteotomy, that allows up to 35° of correction per level. The ideal patient would have a kyphotic deformity at the disc level without a posterior instrumentation spanning the target segment.

INTRODUCTION

Radicular pain with or without low back pain is one of the most common musculoskeletal problems encountered by healthcare professionals. In the majority of cases, nonoperative treatment is sufficient for adequate pain control until resolution of symptoms. When the expected benefits of nonoperative and operative treatment are equal, patients tend to prefer the nonoperative approach due to perceived higher risks of surgery.¹ Despite extensive research, many questions still remain on the optimal nonoperative treatment of patients with radicular pain. First, does nonoperative treatment offer any benefits compared with the natural course of the symptom? Second, are some treatment options clearly more effective than others in diminishing pain and improving function in a patient suffering from acute lumbar radiculopathy? Third, are there any inherent risks associated with nonoperative treatment, and for how long should it be continued before deemed as either successful or failed? Finally, is it possible to identify early on those patients who will respond to nonoperative treatment as opposed to those who will eventually need surgery?

In search of answers to these questions, the following chapter will review the best available evidence on the natural course of radicular symptoms due to a lumbar disc

herniation (LDH), the indications for nonoperative treatment, the effectiveness of nonoperative treatment options, and the possible risks associated with them. This review will be restricted to therapies not violating the confines of the disc space, i.e. any intradiscal techniques are out of the scope of this review.

NATURAL HISTORY OF LUMBAR DISC HERNIATION

Knowledge of the natural history of any clinical condition plays an important role in decisions of whether and how to treat that condition. The treatment should offer clear benefits over the natural course of the disorder without predisposing the patient to unnecessary risks. The natural history of symptoms due to LDH is still inadequately described; in a significant number of patients, the symptoms resolve spontaneously with no formal contact with the health care system, and, thus, without definite diagnosis.

The natural history of an LDH is usually benign, with the majority of patients showing spontaneous resolution of symptoms within a few weeks. Indeed, marked reduction of pain and improvement in function has been shown with no specific treatment in 70% of patients at 4 weeks after the onset of symptoms.² In one prospective observational study with minimal nonoperative intervention, 36%

Figs. 73.1A and B: (A) A left-sided lumbar disc herniation at the presacral level in a 26-year-old woman; (B) One year after the onset of symptoms, the disc herniation has spontaneously reabsorbed. The patient still had residual low back pain radiating to her posterior thighs.

of the patients showed major improvement at 2 weeks, and, after 12 weeks, 73% of patients had experienced at least reasonable improvement.³ However, some evidence suggests that the prognosis of severe sciatica is not as favorable as previously thought, with a significant number of patients still reporting radicular pain at follow-up regardless of the treatment received.^{4,5}

Many LDHs demonstrate a tendency toward natural resorption (Figs. 73.1A and B). The mechanism by which this happens is not fully understood, but macrophage phagocytosis and inflammation are believed to be the most important underlying phenomena. Magnetic resonance imaging (MRI) 12–19 months after the onset of symptoms has shown either a complete resorption or at least a significant reduction in herniation volume in 76–88% of patients.^{6,7} Larger disc herniations, especially sequestered or extruded fragments, seem to have the greatest tendency toward spontaneous resorption over time.^{7–9} Interestingly, no clear correlation between the decrease in disc herniation size and the patient's clinical improvement has been demonstrated.^{8–10}

INDICATIONS FOR NONOPERATIVE TREATMENT

Patients with radicular symptoms and a possible LDH can be treated nonoperatively if they do not show signs of a progressive neurological deficit or cauda equina syndrome.^{11–13} If the patient's radicular pain can be controlled

with nonoperative means, the treatment chosen should interfere as little as possible with the natural resolution of the symptoms.⁶

In clinical practice, patients with radicular pain rarely need imaging of the spine before treatment decisions, and MRI does not have any significant value in planning the initial nonoperative care.¹⁰ Initially, the treatment should be directed at reducing the patient's radicular symptoms, and further diagnostics are reserved for those patients whose signs and symptoms do not resolve with 6 weeks of nonoperative treatment. Magnetic resonance imaging in patients with a 6-week history of radicular symptoms has shown an LDH in two thirds of these patients.¹⁰ Earlier imaging of the spine is indicated if the patient's history or clinical findings suggest a malignancy, infection, or trauma (red flags, Table 73.1), or if the symptoms raise a suspicion of a cauda equina syndrome or progression of a neurological deficit during the observation period.¹⁴ Patients with red-flag findings are usually easily distinguished from those patients with more benign etiology for their radicular pain.

A progressive or significant neurological deficit is generally accepted as a contraindication for nonoperative treatment.^{11–13} Nevertheless, significant recovery of nonprogressive muscle weakness has been reported without surgical intervention. In one prospective observational study, 56% of patients with clinically significant muscle weakness for <1 month were spontaneously improved at 6-month follow-up, and 40% had a complete recovery of their muscle deficit.¹⁵ Bush et al. reported a partial or com-

Table 73.1: Red-flag findings in patients with radicular symptoms indicating a need for advanced imaging of the spine.¹⁴

Findings suggestive of fracture	Significant trauma at any age Minor trauma at older age Age > 70 years Osteoporosis Prolonged use of corticosteroids
Findings suggestive of malignancy	Age < 20 years or > 55 years History of previous malignancy Pain not related to activity General symptoms (weight loss, fever)
Findings suggestive of infection	General symptoms (fever) Pain not related to activity Use of predisposing drugs (corticosteroids, immunosuppressive agents) Use of intravenous drugs
Findings suggestive of cauda equina	Saddle anesthesia Widespread muscle weakness Fecal incontinence Urinary retention or paradoxical incontinence due to overflow
Findings suggestive of failed nonoperative treatment	Progress of neurological deficits Excruciating pain No improvement after 6 weeks of nonoperative treatment

plete recovery of neurological signs in almost all of their patients at 1-year follow-up.⁶ Despite these favorable clinical reports, there is no evidence to suggest that nonoperative treatment would have a positive effect on the natural history of muscle weakness or, indeed, that early surgical treatment would improve the chances of recovery.¹⁶ The clinical course of nonprogressive muscle weakness seems to be of natural resolution in a significant proportion of patients, irrespective of the treatment chosen.¹⁵ Nevertheless, severe muscle weakness for longer than 1 month has been shown to decrease the rate of full recovery after surgical treatment.¹⁷ In conclusion, nonprogressive muscle weakness is not an absolute contraindication for nonoperative treatment, but, in clinical practice, surgical treatment is usually considered if no recovery occurs within 3 months.^{16,17}

There is no consensus on how long nonoperative treatment should be continued before considering surgery in those patients who do not respond to nonoperative means, but do not have an absolute indication for surgery. Furthermore, we do not know whether there is a time window after which permanent damage to the compressed nerve root will cause residual symptoms despite adequate

treatment. Most spine practitioners agree that at least 6–8 weeks should be reserved for nonoperative treatment in the absence of absolute indications for surgery.¹¹ In his classic randomized controlled trial (RCT) comparing nonoperative and operative treatment of LDH, Weber concluded that a minimum 3-month period of nonoperative treatment was necessary to make any decisions on its effectiveness.¹⁸ In another RCT, Peul et al. compared early surgery to 6 months of continued nonoperative care and eventual surgery if needed and concluded that prolonged nonoperative treatment did not increase the risk of unsatisfactory outcome at 2-year follow-up.¹⁹ On the other hand, some recent evidence from the Spine Patient Outcomes Research Trial (SPORT) indicated that although there was no harm in trying nonoperative treatment before surgery, patients with symptoms for >6 months had a better outcome after surgery compared with nonoperative treatment.²⁰ In conclusion, no general rules regarding the duration of nonoperative treatment and the optimal timing for eventual surgery exist, and all decisions must be individualized for every patient.

OUTCOMES OF NONOPERATIVE TREATMENT

Numerous nonoperative treatment options are available for patients with a symptomatic LDH, and many of these have been evaluated under randomized controlled study designs. Yet, the available data are insufficient and at best conflicting, making it difficult to give any evidence-based treatment recommendations.

In an RCT comparing surgical treatment of LDH with nonoperative treatment consisting of mild analgesics and initial bed rest followed by gradual increase of activities, Weber reported that 1 year after the symptom onset, 25% of the nonoperatively treated patients were symptom free and 36% showed satisfactory improvement of their symptoms.¹⁸ In the long-term, up to 10 years of follow-up, the nonoperative group continued to improve with variable recovery patterns. Similar continued improvement with nonoperative treatment was observed in the prospective observational Maine Lumbar Spine Study.^{21–23} With a wide variety of nonoperative treatments, 43% of patients at 1 year after the onset of symptoms, 56% at 5 years, and 61% at 10 years reported their predominant clinical symptom either improved or completely gone. In a more recent prospective study including 340 patients with nonoperative treatment, 41% of the patients reported a successful outcome at 1-year follow-up.²⁴

In summary, significant improvement of symptoms can be expected in 40–60% of patients with different nonoperative treatment strategies. However, there remains a group of patients with substantial symptoms interfering with their daily life after an initial episode of radicular pain. Nykvist et al. reported less favorable long-term results in patients with severe radicular pain at presentation.⁴ At 1-, 5- and 13-year follow-up, 81%, 82%, and 68% of their patients, respectively, suffered from radicular pain regardless of the initial treatment. Further, some evidence suggests that those patients referred to secondary care, either for more severe or continuing symptoms, have a worse prognosis than previously thought; subsequently, 54% and 47% of patients reporting significant radicular pain, and 47% and 39% sustained significant disability at 1 and 2 years after the onset of symptoms, respectively.⁵

Several RCTs have compared the outcomes of operative and nonoperative treatment in well-defined patient populations with LDH.^{19,25–28} A common finding in all these trials has been that although operative treatment seems to result in a faster relief of symptoms, at 1- to 2-year follow-up no significant differences between the treatment groups have been demonstrated. Specifically, Peul et al. noticed a slower and linear recovery in the group receiving prolonged nonoperative care with a median time for recovery of 12 weeks compared with 4 weeks after operative treatment.²⁵ Nevertheless, after 8 weeks no clinically meaningful differences between the treatment groups could be detected, and 79–81% of their patients had satisfactory results whether treated nonoperatively or operatively.¹⁹ Long-term results from the SPORT study report significant and sustained improvement after nonoperative usual care persisting for at least 4 years.²⁷ In conclusion, these RCTs provide conflicting evidence whether operative treatment offers any significant benefit compared with nonoperative treatment for short- or long-term follow-up.²⁹

Results of observational nonrandomized trials have suggested somewhat worse outcomes after nonoperative treatment when compared with operative treatment, especially for the first year after the onset of symptoms.^{18,21,22,24,30} However, this difference seems to diminish with longer follow-up due to continued improvement of the nonoperatively treated patients.

From a societal perspective nonoperative treatment is less costly than surgery, although the difference in costs is balanced, at least short term, by better outcomes among those patients treated operatively.³¹ On the other hand, the gains in quality of life after operative treatment are relatively limited compared with nonoperative care, and

health economic reasons as such do not support early operative treatment in a patient who would prefer nonoperative treatment.³² Moreover, no significant difference in the return to work rates has been noticed between patients treated nonoperatively or operatively.^{22,23,27}

WHO WILL BENEFIT FROM NONOPERATIVE TREATMENT?

Clinical experience and research evidence has demonstrated that many patients with a symptomatic LDH recover with no specific treatment or with minimal intervention, yet others will proceed to surgery due to persisting and intolerable symptoms. Early identification of those patients who respond to nonoperative treatment as opposed to those who will eventually require operative treatment would significantly benefit our spine practices. Some predictors of outcome have been reported in the literature, but the evidence remains inconclusive. Shorter duration of radicular pain at presentation has been identified as a positive predictor regarding success of nonoperative treatment.^{20,24,33} However, in an RCT comparing active “symptom-guided exercises” to sham exercises, patients still improved after months of radicular pain when they received appropriate nonoperative treatment.³⁴ Regarding the prognostic value of the intensity of the radicular pain, or morphology (size and type) of the LDH, a recent systematic review found conflicting evidence.³⁵ Psychosocial factors may be the strongest predictors of outcome,^{5,36} moreover, patients with higher levels of education demonstrated better outcomes after nonoperative treatment than those with lower levels of education.³⁷ Some evidence suggests that even genetic factors affect the individual patient’s response to nonoperative treatment.³⁸

FAILURE OF NONOPERATIVE TREATMENT

Most spine practitioners offer the possibility of operative treatment to those patients who do not respond to nonoperative treatment, although no consensus exists as for how long nonoperative treatment should be continued until it is deemed failed. Variable surgical rates have been reported in groups of patients who initially chose nonoperative treatment for their radicular symptoms. In general, during the first 6–12 months after the onset of symptoms, 2–14% of nonoperatively treated patients opt for eventual surgery.^{4,6,10,21} In the observational cohort of the SPORT

study, 9%, 16%, 22%, and 24% of patients from the nonoperative treatment group decided upon operative treatment by the 3-month, 6-month, 2-year, and 4-year follow-up, respectively.³⁰ Significantly higher failure rates of nonoperative treatment (i.e. surgery rates) have been noticed in a secondary care setting, with 29% of patients at 1 year and 32% at 2 years having undergone surgery for their symptoms.⁵ In all the published RCTs, a significant proportion of patients from the nonoperative treatment arm actually received operative treatment (from 26% to 45% depending on the follow-up time).^{18,19,26,28}

Although the natural course of symptoms due to an LDH is usually benign and self-limiting, many patients experience residual pain and functional limitations after an index episode.^{24,39} In a group of patients with a massive LDH, 85% of the patients reported a satisfactory recovery at 23-month follow-up, but 29% of them still complained of occasional or intermittent low back pain, and 14% suffered from radicular pain.⁸ Significantly higher rates of residual radicular pain, in up to 88% of patients, have been reported from a secondary care setting.⁴⁰ Furthermore, recurrence of radicular pain is relatively common after nonoperative treatment of LDH, with every fourth patient reporting subsequent pain episodes 1 year after resolution of the initial symptoms.³⁹ Recurrence of symptoms was related to a longer time to resolution of the initial pain. Although residual or recurrent radicular pain and functional limitations are possible after nonoperative treatment of LDH, early operative treatment does not seem to diminish the risk of unsatisfactory outcome in the long-term follow-up.^{4,5,19}

Permanent damage to the nerve root or development of a cauda equina syndrome is feared complications of nonoperative treatment. In the randomized cohort of the SPORT study, no patient in the nonoperative usual care group developed a cauda equina syndrome by the 2-year followup,²⁶ and, over 4 years after the onset of symptoms, no evidence of harm from the nonoperative approach could be demonstrated.²⁷ In their RCT comparing early surgery to 6 months of nonoperative care and eventual operation after that period only if needed, Peul et al. could not show that prolonged nonoperative treatment (i.e. delayed surgery) resulted in worse treatment outcomes¹⁹—this might suggest that no permanent damage to the nerve root had occurred. Rather, with the strategy of continued nonoperative treatment, 56% of their patients did not require surgery for satisfactory recovery.

ARE SOME NONOPERATIVE TREATMENT METHODS MORE EFFECTIVE THAN OTHERS?

A wide range of nonoperative treatment strategies are available for the patients with a symptomatic LDH, and many of these have been evaluated in RCTs. However, no standardized treatment protocol exists for these patients. Further, the current evidence on the effectiveness of different treatment options and, indeed, their impact on the prognosis of the clinical symptoms remain limited. The following section will summarize the available evidence regarding the specific interventions frequently applied by spine practitioners and physical therapists for patients with radicular symptoms.

Despite their extensive use for radicular pain, medications have not been widely studied in this patient group. No evidence exists on the effectiveness of nonsteroidal anti-inflammatory drugs (NSAIDs) over placebo.⁴¹⁻⁴³ Due to their anti-inflammatory properties, steroids are sometimes used orally or intramuscularly for pain control. However, oral steroids have not been shown superior to placebo,⁴⁴ and no evidence exists to support the use of intramuscular corticosteroid injections.⁴³ Benzodiazepines should not be used routinely in patients with LDH. In an RCT comparing the efficacy of benzodiazepines with placebo, the probability of significant pain reduction was twice as high in patients treated with placebo compared with patients receiving benzodiazepines.⁴⁵ No evidence supports the effectiveness of opioid analgesics, muscle relaxants, antiepileptic drugs, or tricyclic antidepressants in the treatment of patients with a symptomatic LDH.

Traditionally immobilization has been subscribed to those patients with disabling clinical symptoms. The use of lumbar corsets is not supported by research evidence.⁴¹ Moreover, a systematic review on the effectiveness of nonoperative treatment for radicular symptoms concluded that compared with no treatment, bed rest did not lead to significant improvement in pain or disability.⁴² Specifically, Hofstee et al. compared continuation of daily activities with either physiotherapy or bed rest under randomized controlled study design and noticed that patients receiving either physiotherapy or bed rest did not have a more favorable recovery than patients continuing with their normal daily activities.⁴⁶ Another RCT corroborated that bed rest is not more effective than watchful waiting.⁴⁷

A wide range of physical therapy modalities are being used for patients with radicular symptoms with little evidence supporting their use in general, or any benefit from one treatment strategy compared with others. A recent systematic review suggested that specific stabilization exercise programs would be more effective than watchful waiting in reducing pain at short-term follow-up.⁴¹ Another systematic review found no difference regarding pain and disability at short- or intermediate-term follow-up when comparing physiotherapy with inactive treatment.⁴² Conflicting evidence exists on the effectiveness of physiotherapy compared with other nonoperative care for the overall improvement of the patients, the pain intensity, or working ability at short-term follow-up.⁴² Luijsterburg et al. performed an RCT comparing general practitioner's care (information and advice, pain medication) with physiotherapy in 135 patients with radicular symptoms.⁴⁸ The average patient benefited very little from adding physiotherapy to the general practitioner's care, but for those patients with severe disability the additional physiotherapy seemed to be effective regarding overall improvement. Finally, some evidence suggests that the frequently applied passive techniques to address pain and muscle spasm (e.g. ultrasound and massage) may in fact hinder the patient's recovery.⁴⁹

When comparing manipulation with other nonoperative care, no difference has been reported regarding overall improvement of the symptoms, pain, or return to work at short-term follow-up.^{41,42} In a specific group of patients with an acute LDH and an intact annulus, manipulation was more effective than simulated manipulation for the intensity of radicular pain.⁴¹ However, some concerns remain over the possibility of manipulation exacerbating the symptoms of LDH or causing a cauda equina syndrome. Anecdotal clinical evidence has been published,⁵⁰ although it is often difficult to verify a temporal relationship between the manipulation procedure and the onset of clinical symptoms. Literature suggests that the risk of an iatrogenic cauda equina syndrome with spinal manipulation is as low as 1 in 3.7 million procedures.⁵¹

No significant effect has been demonstrated for mechanical traction in the treatment of patients with a symptomatic LDH.⁴³ Traction was not more effective than sham traction in reducing pain or improving function at short-term follow-up,⁴² and no significant benefit has been demonstrated for traction over other nonoperative treatment methods.^{41,42}

No evidence exists on the effectiveness of acupuncture in the treatment of radicular symptoms due to an LDH.

In summary, very little evidence exists on the above-mentioned treatment methods frequently used for patients with radicular pain, either on the overall effectiveness of those treatments on the patient's symptoms or on the effectiveness of one treatment method over the others. Some frequently used modalities may even be detrimental to the patient's recovery.

■ EPIDURAL INJECTIONS

For decades, ischemia due to mechanical compression of the nerve root was considered the main factor resulting in radicular pain. Our current understanding emphasizes several biochemical inflammatory mediators within the degenerated disc fragments sensitizing the nerve root to the mechanical effects of the disc herniation. In an in vivo animal model, the combination of chronic compression of the nerve root and application of nucleus pulposus material on it caused a more pronounced nerve injury than either alone.⁵² The importance of inflammation in the pathogenesis of radicular pain has led to the use of steroids with or without local anesthetics, administered either into the epidural or transforaminal space, in the treatment of radicular pain. Although the mechanism of action of steroids is not fully understood, they have been associated with anti-inflammatory properties resulting in decreased levels of inflammatory mediators.^{53,54} Interestingly, the anti-inflammatory properties of local anesthetics may even be superior to those of NSAIDs or steroids.⁵⁵

Although a substantial rise in the clinical use of epidural injections has been reported,⁵⁶ their role in the treatment of patients with radicular pain remains controversial. Despite active research, no consensus has been reached on the content and optimal volume of the steroid, the role of local anesthetics, the technical performance of the procedure, or the benefit of repeated injections. Interpreting the published literature is difficult due to differences in type and dosage of steroid used, whether repeated injections were administered or not, heterogeneity of patient populations and outcome variables, and different injection techniques. Due to conflicting evidence on the efficacy of epidural injections in patients with radicular symptoms, some authors do not recommend their use in this patient population.⁴²

Epidural injections have been suggested to those patients who continue to have disabling radicular symptoms despite 6 weeks of appropriate nonoperative treatment,

and in whom the nerve root compression demonstrated by advanced imaging correlates with symptoms and clinical findings.⁵⁷ However, identifying those patients, among the large group of patients with radicular symptoms, who would benefit most from epidural injections remains challenging.⁴⁰ Absolute contraindications for epidural injections include coagulopathy, local or systemic infection, spinal malignancy, or uncontrolled diabetes mellitus.⁵⁸ Allergy to the ingredients of the injectate, congestive heart failure, pregnancy, and a history of steroid psychosis should be regarded as relative contraindications to this intervention.⁵⁸

Epidural injections may contain steroid, and local anesthetic or local anesthetic alone can be administered by caudal, interlaminar, or transforaminal routes. Although the transforaminal route is technically more demanding and requires either fluoroscopic or computer tomography control, it has gained popularity in the recent years. Transforaminal epidural injections are thought to be superior to caudal or interlaminar injections due to a better spread of the injectate into close contact with the actual pathology.^{59,60} Indeed, some RCTs have demonstrated significantly better pain relief with the transforaminal approach than the two more traditional routes of administration.^{61,62}

The overall efficacy of epidural injections in radicular pain has been investigated under randomized controlled study designs with conflicting results. Arden et al. compared the efficacy of three repeated epidural injections with steroid and local anesthetic with sham injections of saline, and noticed that at 3 weeks patients in the epidural injection group had a statistically significant improvement in self-reported function compared with the sham injection group.⁴⁰ However, at 6 weeks the benefit of epidural injections had been lost, and no significant difference in the intensity of leg pain was reported at any of the subsequent follow-up time points. In another RCT comparing epidural injections of steroid and local anesthetic with trigger point injections of saline, 84% of patients in the epidural injection group and 48% in the control group reported improvement in their symptoms with maximal improvement within 6 and 12 weeks, respectively.⁶³ Buttermann randomized patients into either operative treatment or up to three injections of epidural steroids and reported that the degree of improvement in the epidural injection group was similar to that of the surgical group.⁶⁴ Karppinen et al. studied the efficacy of a single nerve root injection in a group of patients with radicular pain randomized to either an injection of steroid and local anesthetic or of saline.⁶⁵ They showed that transforaminal injection with

steroid and local anesthetic was superior to saline injection in terms of pain relief at 2-week follow-up, but not at longer follow-up for up to 1 year. In another RCT comparing injections of steroid and local anesthetic with injections of local anesthetic alone, 54% of patients reported significant pain relief up to 3 months after the treatment.^{66,67}

In vivo animal studies have shown that a combination of steroid and local anesthetic in selective nerve root injections does not result in synergistic actions in preventing pain due to an experimental LDH, thus suggesting that steroids might be unnecessary for selective nerve root injections.⁶⁸ Randomized control trials comparing these two treatment strategies in patients with radicular pain have reported similar findings—no additional benefit from steroids compared with local anesthetic alone.^{69,70} Nevertheless, Riew et al. reported that while selective nerve root injections in general were effective in obviating the need for surgery in surgical candidates with an LDH (Fig. 73.2), those patients who received injections of steroid and local anesthetic were significantly more likely to avoid an operation than patients who received local anesthetic alone.⁷¹

On the other hand, some studies have shown no significant difference in pain relief or disability, either short term or long term, between patients who did or did not receive epidural injections for their radicular pain.^{62,72} In summary, no strong evidence either for or against the efficacy of epidural injections has been published.⁷³ With repeated epidural injections, about half of the patients experience an improvement in their clinical condition.⁷⁴⁻⁷⁶ The possible benefit in patients with an LDH seems to be short term at best.⁴⁰

Fig. 73.2: Selective nerve root injection administered under low-dose computed tomography guidance into the left S1 foramen.

Regardless of the route of administration, epidural injections may give rise to complications due to either technical problems with the injection itself or side effects of the injected steroids. Minor complications have been reported in approximately 10% of patients, with increased pain, facial flushing, and systemic effects of the steroid (elevated blood glucose levels in patients with diabetes, elevated blood pressure, fluid retention, menstrual abnormalities) being the most common.⁷⁷⁻⁸⁰ Dural punctures have been reported in 2-5% of epidural injections; epidural abscesses or hematomas are rare.^{73,81} Although most clinical studies on epidural injections do not report any major complications,^{40,57,59,74,79,80,82} anecdotal case reports of sudden paraplegia immediately after a transforaminal epidural steroid injection have been published.⁸³

In summary, in a subgroup of symptomatic patients with an LDH, epidural injections are effective in relieving pain and improving function. However, the benefit is of short duration, and long-term results probably do not differ from the natural course of the symptom. Although minor side effects are relatively common and usually related to steroid administration, major complications are rarely reported.⁸⁴⁻⁸⁶

TARGETED ANTI-INFLAMMATORY THERAPIES

Biochemical inflammatory mediators originating from the degenerated disc are believed to be important in sensitizing the affected nerve root to the mechanical pressure by the LDH. Animal studies have linked the proinflammatory cytokine tumor necrosis factor alpha (TNF- α) to the nucleus pulposus-induced nerve root injury,^{87,88} suggesting that the injury could be prevented by selective TNF- α inhibition.⁸⁹

Karppinen et al. published promising results from their open-label study treating 10 patients with a symptomatic LDH with intravenous infliximab, a monoclonal antibody against TNF- α .^{90,91} However, in a subsequent RCT comparing intravenous infliximab with intravenous saline, the reduction in radicular pain did not differ significantly between the two groups at any of the follow-up time points up to 1 year.^{92,93} The intravenous saline infusion was remarkably effective in decreasing radicular pain immediately after the intervention, possibly reflecting a powerful placebo effect.⁹² It has been suggested that systemic administration of anti-TNF- α therapy may not be as effective as local administration.⁹⁴ Okoro et al. compared

subcutaneous injections of etanercept, another TNF- α antibody, into the perispinal area to saline injections and concluded that etanercept did not bring any additional benefit over placebo.⁹⁵ Moreover, the third monoclonal antibody against TNF- α , adalimumab, when administered subcutaneously, produced significant differences in pain relief over placebo only during the first 2 days after the treatment.⁹⁶ Finally, when etanercept was administered into the epidural space by the transforaminal route and compared with an identical saline injection, no significant differences in pain relief and disability could be shown between the two groups at 1-month follow-up.⁹⁴

Despite sound theoretical basis and promising preliminary results, the RCTs summarized above do not support the use of anti-TNF- α therapy in patients with a symptomatic LDH. It may well be that several other proinflammatory cytokines besides TNF- α explain the effects of nucleus pulposus on the nerve root.⁹⁷ Indeed, interleukin 1 beta (IL-1 β) and IL-6 have been detected in the paravertebral muscles, annulus fibrosus, and nucleus pulposus of patients with a symptomatic LDH.⁹⁸ A critical time window for an anti-TNF- α therapy may also exist, as the effect of TNF- α seems to be limited to the early stages of the inflammatory cascade.^{93,97} Finally, elevated levels of proinflammatory cytokines (IL-1 β , IL-6, or TNF- α) do not correlate with the intensity of pain,^{98,99} which might at least partly explain the lack of significant pain relief after anti-TNF- α therapy.

In summary, based on best available evidence, TNF- α antibodies should not be used in patients with a symptomatic LDH.

KEY POINTS

- The natural history of LDH-induced radiculopathy is typically a self-limiting process. Rarely is this condition associated with a significant neurological deficit. Natural course of LDH-induced radicular pain is benign and self-limiting in most patients, with larger herniations tending to reabsorb over time.
- Nonoperative treatment of patients with a symptomatic LDH consists of educating the patient on the nature of their condition and the natural course of the symptoms. Treatment should focus on adequate pain control and advice to continue with the normal activities of daily living until the process resolves.
- Numerous nonoperative treatment strategies are available for patients with a symptomatic LDH, but

evidence of their effectiveness remains insufficient. No single intervention is proven superior to the others.

- Currently available nonoperative treatments probably do not affect the natural course of LDH-induced radicular pain, and ideally the treatment should interfere with the natural course of the symptom as little as possible.
- Patients undergoing surgery for LDH-induced radiculopathy have a more rapid resolution of their symptoms when compared with their nonoperative counterparts but at 1- and 2-year follow-up no significant difference between operatively and nonoperatively treated patients has been shown.

“As you leave the OR after an apparently successful microdiscectomy, remember that a successful surgical outcome depends 90% on patient selection and only 10% on technique.”

—John A McCulloch¹

INTRODUCTION

Microsurgical versus Nonmicrosurgical Techniques

The spectrum of open surgical treatment of lumbar disc herniations (DH) ranges from conventional technique without optical magnification, to the use of surgical loupes or microscopy. Although there is a still ongoing debate about the benefits of the use of microscopy for discectomy for the medium and long-term outcome, the short-term advantages include less damage to the paravertebral muscles, decreased blood loss, and reduced postoperative morbidity. These benefits far outweigh the relative disadvantages such as the learning curve.²⁻⁵ In our experience, once this hurdle has been overcome, there is no reason to operate without the aid of a microscope. The surgical techniques described in this chapter are best performed with the aid of the microscope, although they are feasible also with loupes.

Fragmentectomy versus Discectomy

When symptoms are caused by an extruded disc fragment, the disc space should not be cleared. The removal of disc

material from the disc space does not lower the recurrence rate for an extruded fragment, but may increase the post-surgical back pain due to segmental instability.^{6,7}

Subperiosteal versus Transmuscular Approach

The subperiosteal (SP) approach requires the incision or retraction of the ligamentous insertions of the paravertebral muscles from the spinous processes. The iatrogenic intraoperative injury of the posterior supporting structures of the lumbar spine may lead to increased postoperative back pain.⁸⁻¹⁰

The microendoscopic discectomy (MED) technique was introduced by Foley and Smith.¹¹ It was the first technique that addressed the shortcomings of the conventional SP approach. Many investigators have reported that MED is associated with less postoperative pain, a shorter hospital stay, and more rapid return to work.¹²⁻¹⁴ However, MED has some limitations related to a smaller operative field, visualized through a cylindrical tubular retractor.¹⁵

The paraspinal muscle-splitting or “Wiltse” approach along the natural cleavage planes of the paraspinal muscles has shown to cause less damage and retraction

Figs. 74.1A to D: (A) Modified minimally invasive speculum-retractor versus conventional; (B) In site; (C) Expandable tubular retractor with a holding arm; (D) In site.

of the paraspinal muscles compared to the SP approach.¹⁶ This leads to decreased back pain and less postoperative analgesic consumption during the early postoperative period.¹⁰ The choice of the transmuscular (TM) approach may be left to the surgeon's preference in patients with fatty degenerated muscles, and it is recommended whenever minimizing muscle traumatization becomes an issue.

Retractors: Miniaturized (Tubular) versus Conventional

The introduction of TM approaches via tubular or miniaturized speculum-retractors has prompted the development of miniaturized surgical tools, which are sized between the conventional microsurgical instruments and the endoscopic ones. Their design facilitates the

intraoperative view of the surgical target area (Figs. 74.1A to D). Surgical times are comparable to open conventional techniques.

SURGICAL TECHNIQUES

Primary Disc Herniations

Interlaminar Approach^{17,18}

- Indications
 - All contained or extruded disc fragments between the midline and the medial border of the pedicle. In relation to the disc space, the fragments may be caudally or cranially extruded. In the latter case, the translaminar approach is preferred.

Figs. 74.2A and B: Clinical teaching case: A 42-year-old gentleman presented with mild low back pain and severe left-sided L5 pain requiring opioids for 3 weeks. The examination demonstrated a left-sided foot dorsiflexion weakness. (A) Because the axial magnetic resonance imaging—slice L4/L5 was reported as normal, no further therapy was proposed; (B) A large extraforaminal DH L5/S1 (arrow) was overlooked. Complete remission of symptoms after surgical removal of the disc fragment.

- Disc herniation combined with central/lateral recess stenosis or with asymptomatic segmental instability
- Recurrent DH
- Contraindications
 - Foraminal or far lateral DH, which are located lateral to the lateral border of the pedicle.
- Preoperative planning
 - *Biplanar plain radiographs:* Optional in primary cases, provided that the magnetic resonance imaging (MRI) investigation encloses a coronal slice (scoliosis). Mandatory in: (1) recurrent DH cases to evaluate bony defects; (2) whenever the MRI leads to suspicion of a bony abnormality (spina bifida, pars interarticularis defects).
 - *Magnetic resonance imaging sagittal slices:* Contained DH or extruded fragment? Caudal or cranial (suitable for translaminar approach) fragment dislocation? Mid-vertebral body herniation (half-way between two disc spaces)? *Foraminal slice:* Black neuroforamen? *Extraforaminal slice:* Disc fragment still apparent? *Axial slices:* Axillary disc fragment? How much of the DH is underneath the thecal sac, intraforaminal or extraforaminal (Figs. 74.2A and B)? Pseudomeningocele in recurrent disc surgery? *Coronal slices:* Which approach for combined intraforaminal and extraforaminal DH? *Gadolinium-enhanced slices:* Amount of scar tissue on the way to and into the spinal canal? Differentiation between recurrent DH and scar tissue?
 - *Computed tomography (CT) scan:* Secondary choice whenever MRI contraindicated or not available. *Disko-CT* (= discography + CT): Helpful in suspected extraforaminal DH. *Contrast medium-enhanced CT:* indicated for recurrent disc, differentiation between intraforaminal DH and neurinoma.
- Positioning

We recognize that several positions could provide good clinical results, especially with experienced operating room personnel. The details of our preferred positioning technique are described below:

 - The patient is placed prone on the Wilson frame. Advantages: Hip and knee joints are only moderately flexed, especially important in obese patients! The lordosis of the lumbar spine should be reduced as required by increasing the height of the arches. The distance between the arches can be adjusted according to the size of the patient in order to allow a free hanging abdomen to reduce bleeding (Figs. 74.3A to D).
 - The head is positioned into a Prone View mask (Manufacturer: Dupaco, Oceanside, CA). Eyes, nose, and chin are protected: the anesthesiologist is able to check them intraoperatively by the use of a mirror (Figs. 74.3A to D).
 - For safety reasons, the patient is secured with a belt on the gluteal area: this becomes helpful when the operating room (OR) table has to be tilted away

Figs. 74.3A to D: Positioning for open lumbar disc surgery: (A) The face is embedded in an anatomically tailored foam; (B) The mirror enables a continuous monitoring of the eyes and of the tube; (C) The lumbar spine is parallel to the floor. The belts secure the patient during tilting the table 30° away from the surgeon, as required in extraforaminal disc surgery; (D) The Wilson frame can be adjusted according to the size of the patient and may open up the interlaminar window by decreasing the lumbar lordosis.

from the surgeon, e.g. in dealing with extraforaminal or far lateral disc herniations (EFDH).

- The OR table is tilted until the lumbar spine is parallel to the floor.
- *X-ray localization:* A 2-cm skin incision does not allow a “seek and find” surgery. Therefore, the correct X-ray localization of the surgical target area is of paramount importance. The needle is always inserted contralateral to the intended surgical side in order to avoid subcutaneous or intramuscular hematoma, and off the midline in order to prevent inadvertent cerebrospinal fluid (CSF) leakage. The needle is perpendicular to the target area (and to the floor): soft-tissue dissection is easier straightforward down. Even small oblique deviations can lead to the wrong level, especially in obese patients. The needle should point to the equator of the target disc. With increasing experience, the surgical field may be narrowed further to only the extruded disc fragment.
- **Soft-tissue approach**
The interlaminar space can be approached via a SP or a transmuscular/paramedian (TM) route. Although the use of the microscope “from skin to skin” is optional, its advantages will be appreciated in dealing with a miniaturized surgical corridor. The most relevant steps are described here:
 - Prophylactic antibiotic coverage (e.g. cefazolin or cephazolin) 30 minutes before the skin incision.
 - *Skin:* 2 cm incision, 5 mm (SP) or 10 mm (TM) off the midline.
 - *Fascia:* (SP) Slightly semicircular incision toward the midline. Five holding sutures on the medial lip secured to a clamp with weights. (TM) Straight incision with one holding suture on each side.
 - *Muscle:* (SP) Paramedian retraction of the paravertebral muscles from the interspinous ligament. Sharp dissection of the rotators from the lower rim of the superior lamina and from the facet joint capsule. Insertion of a miniaturized speculum-counter-retractor system (Figs. 74.1A and B; manufacturer: Medicon, Tuttlingen, Germany).
 - (TM) Blunt splitting with the index finger until the laminofacet junction can be palpated. Opening of the muscular corridor with miniaturized muscle retractors or with a dilator. Insertion of an expandable tubular retractor (Figs. 74.1C and D; manufacturer: Medicon, Tuttlingen, Germany) to 15 mm or 18 mm diameter. Both the speculum and the tube may be secured to the OR table with a self-holding arm or the “snake” (Figs. 74.1C and D).
 - *Interlaminar space:* From this step onward, the surgical technique is identical. The lower rim of

the cranial lamina, the medial border of the facet joint, and the yellow ligament are the areas of interest. Radiographic confirmation of the level is performed. Following a lateral flavectomy or flavotomy with suspension sutures, the epidural fat is exposed. The medial border of the inferior articular process is undercut or drilled off until the shoulder of the root is palpated.

- *Epidural dissection:* Cranial and caudal dissection of the epidural fat performed with a microdissector and a flat sucker along with careful bipolar coagulation of veins, which opens access to the root-DH complex.
- Exposure of the herniated disc
 - *Management of the DH:* The local anatomy will dictate the necessary steps. Usually, a gentle dissection between root and disc material is accomplished first. In our experience, the root retraction is performed intermittently with a flat sucker instead of with a conventional root retractor. Free disc fragments are removed with miniaturized forceps (Manufacturer: Medicon, Tuttlingen, Germany). If indicated, the annulus is split bluntly with the dissector or with a scalpel and further disc material is removed. In the authors' experience, additional discectomy is performed in 20–30% of the cases.
- Closure
 - The disc space, when opened, is rinsed with normal saline. The opening of the annulus is closed with a collagen sponge coated with fibrinogen and thrombin (Tachosil, Manufacturer: <http://www.Takeda.co.uk>). The epidural fat is mobilized in order to cover the root. Careful hemostasis goes along with closure by layers.

Translaminar Approach¹⁹⁻²³

- Indications
 - Cranially extruded disc fragments pushing the exiting root against the lower rim of the pedicle. Usually they are located within the root canal between two lines marking the medial and lateral border of the superior facet.
 - Recurrent cranially extruded disc fragments of DH previously removed via an interlaminar approach.
- Contraindication
 - Lack of an adequate bony lamina, e.g. severe spinal canal stenosis and spina bifida.
- Preoperative planning
 - *Magnetic resonance imaging (sagittal slices):* Measure the distance between the upper border of the disc

space and the lower rim of the cephalad pedicle. The translaminar hole will be centered on the halfway of this distance. *Axial slices:* Look at how much of the bulk of the DH is underneath the thecal sac and how much is lateral of it or even intraforaminal. The translaminar hole is centered on the lateral border of the dura.

- Positioning
 - Basically the same as for the interlaminar approach
 - *Important:* The target lamina should be parallel to the floor. This may require the surgeon to tilt the OR table in a reverse Trendelenburg position. The advantages of a horizontal target lamina are two-fold: the placement of the retractor blade and the drilling of the hole becomes easier (Figs. 74.6 and 74.7A to D).
 - Radiographic localization: The needle should point to the largest portion of the DH, which is usually halfway between the upper border of the target disc and the lower rim of the cranial pedicle. At the beginning of the learning curve, these landmarks may be labeled on the skin incision.
- Soft-tissue approach
 - The lamina can be approached via a SP or a TM route. The soft-tissue approach mirrors the interlaminar approach. Remember: The width and the overlapping of the lamina in relation to the disc space increase in the caudal-cranial direction, whereas the width of the isthmus decreases. This means that the translaminar hole will be more medially and oval-shaped in the upper lumbar levels (Figs. 74.4A and B).
 - *Lamina:* Irrespective of the type of retractor used, the lateral border of the lamina should be visible underneath the retractor valve. A dissector is placed onto the lamina where the bulk of the DH is suspected and a fluoroscopic localization is performed (Fig. 74.5). At this point, the lamina should have been tilted parallel to the floor, so that the high-speed cutting burr can be held easily perpendicular to the lamina. With slow circular movements, a round (L5) or oval-shaped (L4 and cranially) hole of about 10 mm in diameter is performed (Figs. 74.6 and 74.7A to D). Three layers “white” (outer cortical bone), “red” (spongy bone), and “white” (inner cortical bone) will be drilled off. For the sake of safety, the inner cortical bone should be drilled with a diamond burr. Remarks: (1) At least

Figs. 74.4A and B: Clinical teaching case: (A) The cranially extruded L5/S1 disc fragment (yellow arrow) is a good indication for the translaminal approach; (B) Unfortunately, the surgeon omitted the intraoperative fluoroscopic control after having approached the lamina because he “felt” that it was the right level. The translaminal hole L4 (red arrow) did not show any disc fragment. Following the fluoroscopic check, a new hole was drilled at the L5 level (yellow arrow) and a large disc fragment was removed. Fortunately, the translaminal approach spares the corresponding facet joint. Nevertheless, the intraoperative X-ray confirmation of the correct level before drilling off the bone is a must!

3 mm of the lateral border should be spared in order to avoid a fracture of the pars interarticularis (Fig. 74.6). (2) Usually, the translaminal hole is located just cephalad to the cranial insertion of the yellow ligament. So, after removal of the thin shell of inner cortical bone with small patches, epidural fat will appear.

- *Epidural dissection:* Up and down dissection of the fat along the lateral border of the dura. That should be continued cranial up to the axilla of the exiting root.
- Exposure of the herniated disc
Usually an extruded or subligamentous disc fragment/s can be mobilized. After decompression, the root slips caudally into the visible field (Figs. 74.7A to D). The foramen is then probed with a double-angled hook or blunt probe. If an extensive annular perforation is detected, the disc space should be cleared. In our experience that was required in merely 20% of the cases. The rate of recurrent DH was 7%.
- Closure
 - Gelfoam soaked with a long-acting steroid to fill in the hole is optional, but should be avoided if the disc space has been cleared.

Fig. 74.5: The up-down length of the lamina (white figures) increases, whereas the width of the isthmus (black figures in mm) decreases in the caudal-cranial direction. That means the overlap of the disc by the lamina increases also in the upper lumbar levels. Furthermore, there the translaminal hole becomes more paramedian and oval-shaped.

Extraforaminal or Far Lateral Approach²⁴⁻²⁶

- Indication
 - Disc herniation whose bulk is located at least two-thirds lateral to the pedicle
- Contraindication
 - Foraminal DH located more than two-thirds inside the root canal
- Preoperative planning
 - *Magnetic resonance imaging sagittal slices:* Usually scans are not lateral enough, i.e. lateral to the root canal, and may miss the extraforaminal disc herniation (EFDH). *Axial slices:* compare the amount and distribution of the extraforaminal fat tissue on both sites. *Coronal slices:* although rarely performed, they are of invaluable assistance to show the spatial relationship between exiting root, root canal, and the extraforaminal compartment.
- Positioning
 - Basically the same as for the interlaminar approach
 - For safety reasons, the patient should be belted on the gluteal region: the OR table has to be tilted 20–30° away from the surgeon in order to get a better oblique view of the extraforaminal compartment. Morbidly obese patients may risk “roll over” on to their abdomen.
 - Radiographic localization: Lateral view: Insert a spinal needle one finger’s breadth lateral to the spinous process, perpendicular to the skin and

Fig. 74.6: The three-dimensional computed tomography shows a translamellar hole at L3. *Note:* The facet joint L3/L4 is intact and a sufficient lateral rim (5 mm) of the pars is maintained where the bone is the strongest.

Figs. 74.7A to D: (A) A left-sided 10 mm translamellar hole at L4 with an intact inner cortical bone is seen through the expandable tubular retractor (15 mm Ø); (B) Close-up view showing the lateral part of the dural sac and epidural fat tissue bordering it; (C) Following dissection of the epidural fat, a large extruded disc fragment appears in the axilla of the exiting L4 nerve root; (D) After the removal of the disc fragments, the L4 nerve root slips back into the visible field.

projecting toward the lower border of the affected disc space. Draw a horizontal line at this level (A).

- Anteroposterior view: Two horizontal lines are drawn: (1) The lower border of the affected disc (A); (2) The lower border of the transverse process above the affected disc (B). Two vertical lines are also drawn: (1) The midline [row of the spinous processes] (C); (2) a line about 4 cm off to the midline, marking the lateral boundary of the pedicle above and below the affected disc (D). The distance between the two horizontal lines (AB) is the skin incision and will be 3–4 cm in length and about 4 cm paramedian (Figs. 74.8A to E).

- **Soft-tissue approach**

The paraspinous TM blunt-splitting approach to EFDH at the level L4/L5 or more cranially can be performed with an expandable tubular retractor or with a miniaturized speculum combined with medial and lateral counter-retractor blades. At the level L5/S1, the author recommends the use of two counter-retractors inserted perpendicular to each other. That allows to choose four blades of different lengths matching with the following structures: facet joint (medial), transverse plane (lateral), transverse process (cranial), and ala (caudal) (Figs. 74.9A and B). Furthermore, the use of the microscope “from skin to skin” is advised.

- *Skin*: 3 cm in length 4 cm off the midline.
- *Transmuscular route*: After incision of the fascia of *Musculus erector spinae*, the muscle is dissected bluntly using the index finger along the cleavage plane between the multifidus and the longissimus muscle (Figs. 74.8A to E). If this intermuscular plane cannot be palpated, the muscle is split downward to the medial third of the transverse processes. The selected retractor is then introduced so that the tips rest firmly on the lower half of the upper transverse process and on the upper half of the lower one. The lateral surface of the pars interarticularis represents the medial border of the surgical exposure. Fluoroscopic confirmation at this point of the procedure is essential (Figs. 74.8A to E).
- *Extraforaminal approach*: Tilting the OR table by 20–30° away from the surgeon gives a better view of the area lateral to the pedicle. Drilling off bone is usually not necessary, except in the case of an extremely hypertrophied facet joint or at the L5/S1 level. The medial half of the intertransverse muscle is incised and pushed laterally, thereby exposing the intertransverse membrane, also called the

intertransverse ligament. Use of bipolar cautery is essential to maintain hemostasis and a blood-free surgical field. After incision of the membrane, the fat surrounding the nerve appears. Because of the proximity of the nerve, the accompanying vessels, and DH, the sucker should also be used as a nerve retractor. However, beware of an excessive retraction of the dorsal root ganglion in order to minimize the incidence of postoperative burning dysesthesias, which should be counseled to the patient preoperatively. Branches of the radicular artery should be dissected carefully and spared whenever possible. The accompanying veins can be cauterized, if they hinder the access to the disc fragment.

- **Exposure of the herniated disc**

Management of the DH: Typically, we find the nerve and the ganglion pushed laterally and cranially by the free disc fragment. Usually, removal of the fragment alone is sufficient. If an extensive perforation of the annulus is evident, clearing of the disc space should be considered. After probing the root canal with a double-angled blunt hook for residual fragments, the nerve may be covered with a gelfoam soaked with crystalline steroid.

- **Closure**

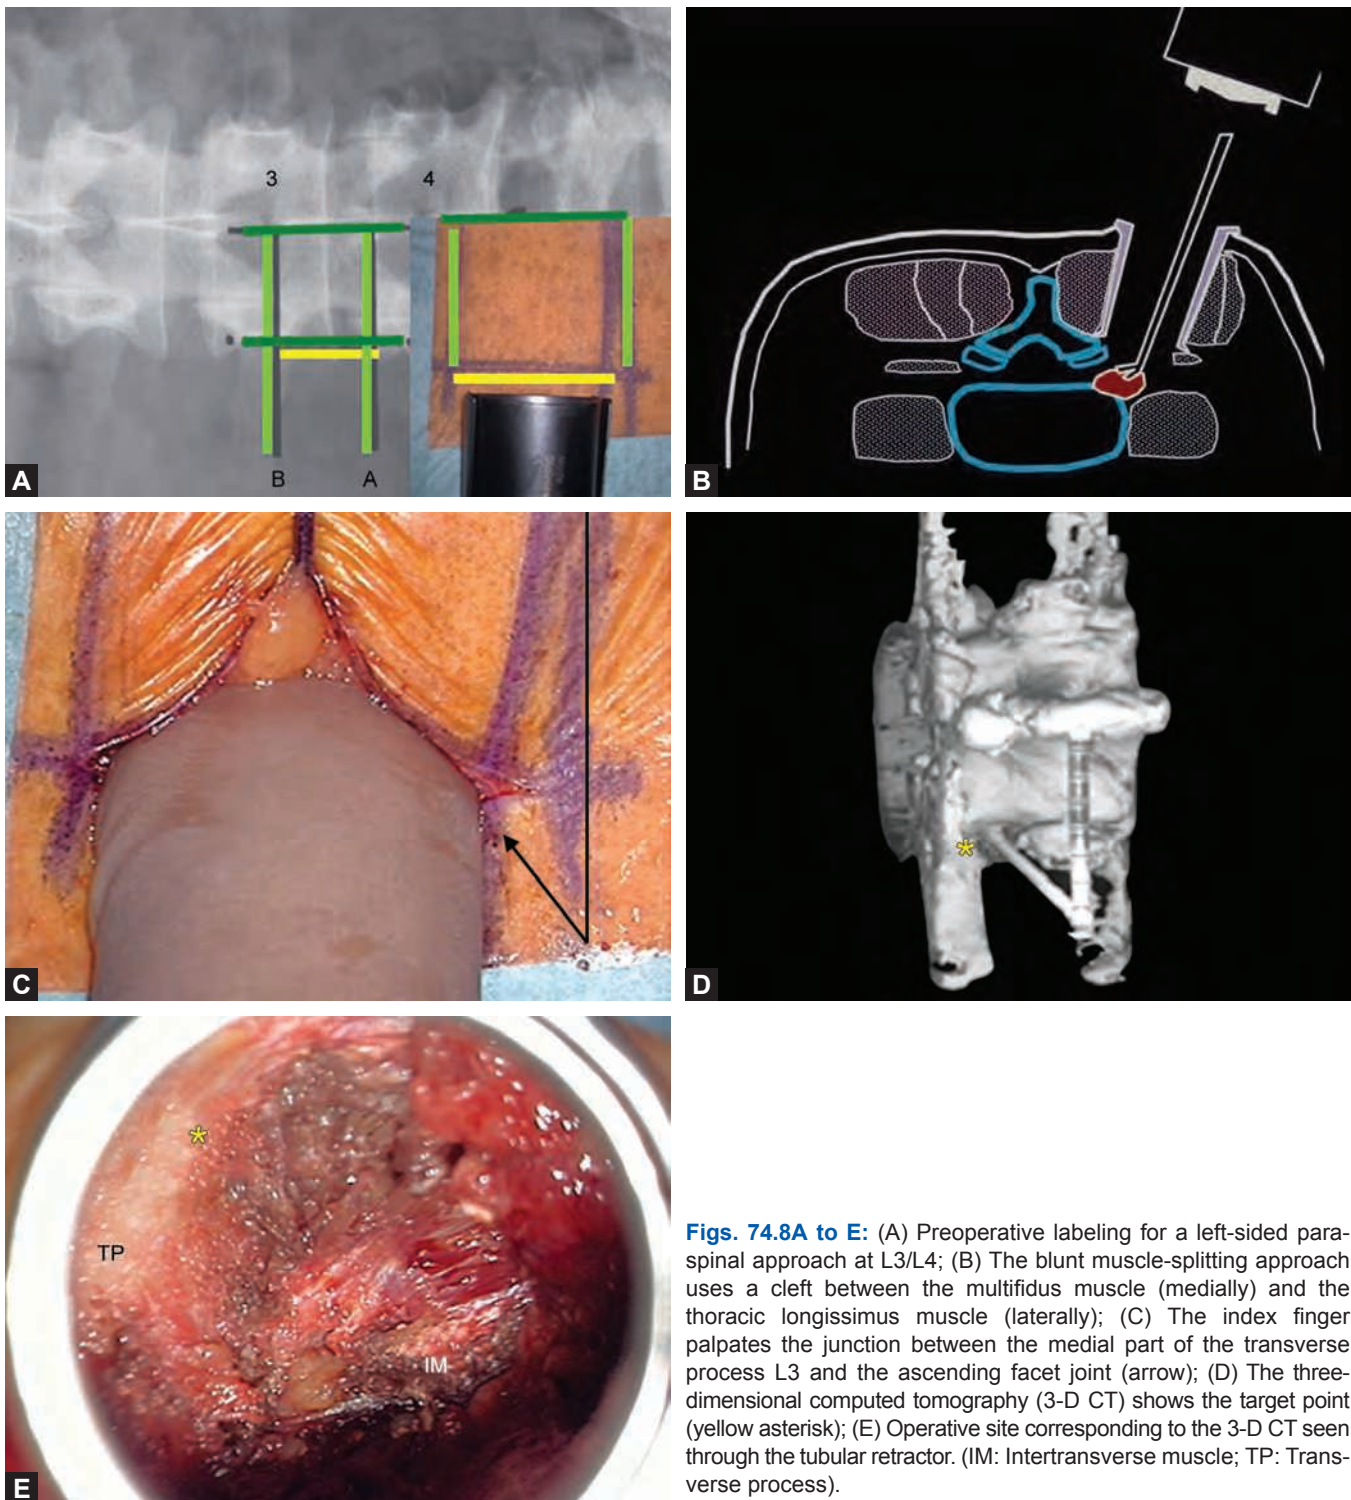

- Placing a drain is optional and in our experience seldom necessary. Muscles do not require suturing.
- *Special considerations for the L5/S1 level*: Because of the particular anatomic relationship between disc space, transverse process L5, and ala, the microsurgical muscle-splitting approach at the lumbo-sacral level should be practiced by a surgeon who is already familiar with the technique at the more cranial levels. Repeated intraoperative fluoroscopic checks may also be necessary. If difficulties arise, switching to the conventional macroapproach should be considered.

Recurrent Disc Herniation^{27,28}

A prevalence of 7–10% recurrent herniations is reported in the literature independently of the surgical technique used. To deal with a recurrent DH usually does not mean to perform a “re-do surgery” identical to the first procedure. The peculiarities of surgery for recurrent DH will be addressed.

- **Preoperative planning**

- The use of the microscope in our view is a must as it facilitates the differentiation between scar tissue and the dural sac.

- Bypassing most of the scar tissue is imperative. This can be achieved either by using a wider approach than the first one exposing the lower edge of the

upper lamina or the medial wall of the pedicle where unscarred dura can be found. The translaminar approach of a recurrent cranially extruded disc

Figs. 74.9A and B: (A) Operative site of a left-sided paraspinous approach L5/S1: Four slim retractor blades of different lengths are inserted. (1) Ascending facet (medial); (2) Thoracic longissimus muscle (lateral); (3) Transverse process L5 (cranial); (4) Ala sacri (caudal); the white arrow shows the point where the nerve L5 is to be expected; (B) Intraoperative fluoroscopic check: the dissector points to the target point (white arrow).

fragment can be used via a virgin translaminar route instead of dissecting the interlaminar scar tissue.

- Preoperative radiographs show the amount of previously resected bone. This is of paramount importance if previous surgery has been performed elsewhere. If doubts persist, the CT scan provides useful information about the bony landmarks that will guide the surgical approach.
- Gadolinium-enhanced MRI shows the relationship between scar tissue and true recurrent disc material and may differentiate the two. However, this holds true if the recurrent DH occurs roughly within 3 years after the first surgery. Furthermore, endplate Modic lesions and CSF collections should also be closely examined.
- Positioning
 - The same as performing virgin surgery.
- Soft-tissue approach
 - Fluoroscopic labeling of the target area is mandatory as the scar of the skin may slip depending on the positioning and on the amount of subcutaneous tissue.
 - Cautious sharp SP dissection is recommended to the interlaminar window. The lower border of the cranial lamina, the medial border of the remnant facet joint, and the upper border of the caudal lamina should be clearly visible.
 - The most commonly used entry point is the area between the cranial border of the epidural scar and the virgin dura. If this approach should fail, the area between the medial border of the pedicle and the shoulder of the traversing root is an alternative option.
- Exposure of the herniated disc
 - A generous decompression of the root in the lateral recess should precede the mobilization of the nerve from the annulus or from the extruded disc fragment. An intraoperative single shot steroid may be helpful at this stage of the procedure by the anesthesiologist.
 - “Peeling” of the fibrous tissue from the nerve carries a high risk of injuring the dura and does not provide a better clinical outcome. Before biting with the Kerrison punch, a light tug may show movement of scarred dura jump: a sentinel sign of an imminent dural tear.
 - The disc space can be entered laterally from the border of the dural sac and cleared. This reduces the pressure on the extruded disc material. Repeated flushing with saline within the disc space may bring further disc material to the surface. We do not recommend curettage of the endplates. The fibrous pocket containing the extruded disc material is opened and its content removed bluntly with straight/angled probes of different length. A tiny fibrous shell is left adherent to the dural sac. There is no evidence that forced “neurolysis” provides a better clinical outcome.

POSTOPERATIVE CARE²⁹

- *Uncomplicated surgery:* The patient is encouraged to leave the bed 6 hours after surgery. Sitting is allowed starting from the first postoperative day. Physiotherapy starts the morning after surgery. Hospital stay is usually 1–3 days.
- *Standard dural repair:* 48 hours of bed rest with the head in slightly Trendelenburg position (head down). If intraoperative loss of CSF was significant, the patient is treated with intravenous hydration + promethazine + analgesic regimen.
- *Very difficult dural repair not watertight at the time of wound closure:* Closed subarachnoid drainage obtained by puncture at one level above the dural opening and the catheter placed at the thoracic-lumbar junction. The amount of CSF can be controlled by the level of the collection bag relative to the lumbar spine. Cerebrospinal fluid drainage can be continued up to 1 week and should cause mild headache.

COMPLICATIONS

The literature lists several “generic” complications such as deep vein thrombosis, pulmonary embolism, and urinary infections that are fortunately rare. Retroperitoneal major vessel injuries and postoperative visual disturbances (risk factors: diabetes mellitus, long operation time) are even more rare.

Microsurgical discectomies have significantly less severe intraoperative complications as compared to non-microsurgical discectomies.³⁰ Experienced surgeons have significantly less complications (2.2%) than beginners (10.7%).³¹ Recurrent surgeries are burdened with a higher incidence of complications.³²

The most common complications of even refined microsurgical techniques are wrong level surgery, dural opening/CSF leakage (2–7%), root injury (0.06 %), and spondylodiscitis (0.4–1%).

Some remarks about the first two pitfalls:

- *Wrong level surgery*
 - The surgical target area should be as much parallel to the floor as possible.
 - Use a spinal needle (for CSF tap: more expensive, but also more radiopaque, especially in adipose patients) perpendicular to the back, one finger’s breadth off the midline, down to the lamina, contralateral to the intended surgical approach, and pointing to the upper rim of the disc space.

- Label the corresponding horizontal line, the midline, and the skin incision.
- Drape the C-arm (lateral view) and park it conveniently in the surgical suite.
- Time out procedure: confirm the correct level and side of surgery.
- Repeat the trajectory of the cannula inserting the retractor. Remember: in overweight patients, a minimally oblique trajectory can lead a surgeon to the wrong level.
- *C-arm:* Check the level before drilling off bone.
- Do not rely on scars in recurrent surgery; mark the skin incision with the aid of radiographic localization.
- The intraoperative threshold for obtaining a fluoroscopic confirmation should be low.

Dural opening

Each dural opening requires a specific treatment depending on location, shape, and size of the lesion, potential concomitant injury of the cauda fibers, microsurgical skills of the surgeon—just to mention the most important factors.

The following acronym “Bird Mc Dove” may aid in remembering a sequence of steps (Figs. 74.10A to D):³⁵

1. **B**one removal until you see the whole dural tear
2. **I**ntradural look
3. **R**epone the nerve roots into the thecal sac, if necessary
4. **D**o an inside patch (e.g. Tachosil with the yellow surface to the dura)
5. **D**ural closure, at best by suturing
6. **O**utside patch (the same as step 4)
7. **V**alsalva maneuver (e.g. 40 cm H₂O × 30 s)
8. **E**pidural pedicled muscle flap (from the paraspinal muscles in order to fill the epidural dead space)
9. **M**ultilayer wound closure (deep muscle layer anchored to the spinous process),
10. **C**erebrospinal fluid drainage, if necessary

Of course not all of the above-mentioned steps are necessary every time. The first goal is to get a watertight closure of the dura (5). Should that fail, then three steps become mandatory: to seal the dural opening (4+6), to achieve a watertight wound closure, (9) and to lower the postoperative CSF pressure (10).²⁹

CRITICAL EVALUATION

“But successful lumbar disc microsurgery is also based on the surgeon’s appreciation of the facts that microsurgery is

Figs. 74.10A to D: (A) Recurrent disc surgery: Intraoperative large dural tear caused by pulling epidural scar tissue. The opening is not suitable for direct repair; (B) The opening has been closed from inside with hemostatic (yellow surface) collagen (Tachosil); (C) The same has been done from the epidural side with the hemostatic yellow surface inside (sandwich technique); (D) A tension-free pedicled epidural muscle flap fills the epidural space. Furthermore, deep anchoring sutures are passed through the spinous process.

not seek-and-find surgery, and that the microscope does not do the surgery.”¹⁸

The first half of the citation stresses the importance of preoperative planning: the careful evaluation of location, size, and shape of the DH, its relationship to the disc space, to the exiting and to the traversing root, to the lateral recess, and to the root or spinal canal requires excellent MRI imaging and dictates the soft-tissue approach and the intraspinal handling of the pathology. A surgical plan tailored for the individual DH becomes necessary. At that point, the small skin incision, reduced muscle traumatization, conservative bone drilling, and plain removal of the offending disc fragment become the practical implementation of the microsurgical philosophy.

The second half of the citation points out that although “small is beautiful,” it should never be an end in itself. Especially at the beginning of the microsurgical learning curve, switching to a larger approach should be considered whenever problems arise. However, with increased experience, all difficult situations will be addressed even more effectively with the aid of the microscope.

The gap that has been bridged between macro- and microsurgery is going to be overcome by the latter and endoscopic spinal techniques. Robotic nanosurgery is waiting behind the corner in the future. The goals do not change: to get a good clinical result with the least iatrogenic trauma.

KEY POINTS

- Even though this chapter has dealt with technical aspects of the surgical treatment of lumbar disc herniations, proper indications with the right technique at the right moment is the most important factor influencing the clinical outcome.
- The use of the microscope provides many advantages.
- The most important aspect of the microsurgical philosophy that supports minimally invasive surgery is the “mental planning” of the procedure beforehand.
- The assumption that one approach fits all subgroups of lumbar disc herniations has been substituted by the conviction that tailored approaches such as the interlaminar, translaminar, and paraspinal approaches address the different pathologies in a less traumatizing manner.
- The use of a paramedian muscle-splitting approach and the use of tubular retractors when available have even further reduced the approach morbidity, especially in obese patients.

KEY REFERENCES

Mc Culloch JA, Young PH. *Essentials of Spinal Microsurgery*, Chapter 20. Philadelphia: Lippincott-Raven; 1998. Microsurgery for lumbar disc herniation; p. 380.
Written by an orthopedic surgeon and a neurosurgeon (quite uncommon at that time!) one and a half decades ago, this book covers the basic principles of microsurgery in an unparalleled way! The sections on the treatment of

lumbar and cervical disc disease are a must for all spine surgeons thinking about utilizing microsurgical techniques.

Mayer HM. Principles of microsurgical discectomy in lumbar disc herniations. In: Mayer HM (Ed). *Minimally Invasive Spine Surgery*. Heidelberg: Springer; 2005. pp. 278-81.

A multiauthored and complete survey of all microsurgical and endoscopic techniques is given. The chapter addresses terminology, history, surgical principles, advantages/disadvantages, indications, access principles, complications, and results, which educates the reader familiar with all types of new minimally invasive techniques in clinical use.

Schiefer W, Klinger M, Brock M, et al. A new surgical procedure for lumbar disc herniation causing less tissue damage through a microsurgical approach. In: *Advances in Neurosurgery*, Vol 4. Berlin: Springer; 1977. pp. 74-80.

The microsurgical treatment of lumbar DH was born and became a new frontier in this article! On page 81-82 of the same Volume of the same Journal, MG Yasargil reported his microsurgical experience with 105 lumbar disc patients. One year later, RW Williams published in *Spine* "Microlumbar discectomy: A conservative surgical approach to the virgin herniated disc."

Foley KT, Smith MM. Microendoscopic discectomy. *Tech Neurosurg*. 1997;3:301-7.

This article reports for the first time the technical aspects of the new procedure. Microendoscopic discectomy is performed by a muscle-splitting approach using a tubular retractor. A specially designed endoscope is placed inside the tubular retractor while the surgeon views the procedure on a video monitor. Nowadays, expandable tubular retractors are available and surgery may be performed with the microscope, thereby shortening the learning curve. The clinical advantage of less traumatization of the muscle tissue and of less bleeding is maintained.

Di Lorenzo N, Porta F, Onnis G, et al. Pars interarticularis fenestration in the treatment of foraminal lumbar disc herniation: a further surgical approach. *Neurosurg*. 1998;42:87-90.

In this paper, the translaminar approach to cranial extruded lumbar disc herniations has been reported for the first time. At that time, the comments enclosed concerns about the limited exposure and the difficulty of the procedure, the potential risk of early or late fracture of the pars interarticularis, and the assumed inability to clear the disc space. Fortunately, 14 years later, this approach has proven to be straightforward, to spare the facet and the yellow ligament, and to be the first choice for the treatment of foraminal DHs.

Cauda Equina and Conus Medullaris Syndrome

INTRODUCTION

Cauda equina syndrome (CES) and conus medullaris syndrome (CMS) are rare neurologic disorders that result from the dysfunction of sacral nerve roots in the vertebral canal resulting in impairment of bladder, bowel, or sexual function. Typical manifestations of CES include low back pain, unilateral or bilateral sciatica, bilateral lower extremity weakness, saddle or perianal anesthesia, as well as rectal and bladder sphincter dysfunction.¹ Typical manifestations of CMS are similar without the motor disturbances in the lower extremities and with sensory disturbances limited to sacral dermatomes.²

Cauda equina syndrome is a rare disorder with equal incidence among males and females. The incidence of CES is variably reported and depends on its etiology. It has been implicated in 2–6% of lumbar disc operations and has been estimated in the general population to occur with an incidence of 1 in 33,000–100,000.^{3–5} Its recognition is often delayed as its manifestations of bladder, bowel, and sexual complaints have a variety of other possible causes. Additionally, a patient's hesitation to mention these symptoms due to embarrassment or because of insidious onset may contribute to the delay in diagnosis. Isolated CMS is even less common than CES and almost always associated with intradural pathology such as tumors or vascular lesions. Compressive lesions at the level of the conus medullaris will almost always compress the cauda equina as well and give rise to a mixed picture.

PATHOPHYSIOLOGY

The spinal cord terminates at approximately the level of the intervertebral disc between first and second lumbar vertebrae and forms the conus medullaris. The conus medullaris consists of the myelomeres of the five sacral nerve roots and represents a transition zone from central to peripheral nervous system. Whereas the roots of the upper cervical nerves maintain their initial embryonic position, the progressive differential growth between the cord and spinal column pulls the lumbosacral roots inferiorly in an increasingly oblique direction. The cauda equina consists of this bundle of nerve roots distal to the conus medullaris, which have been drawn inferiorly during fetal development. The motor fiber components of each nerve root are found anteromedially and the larger sensory components are located posterolaterally.⁶

The pathophysiology behind CES is at present still unclear. Arterial injection studies have suggested that each lumbosacral root receives its own blood supply from both distal and proximal radicular arteries that anastomose in the proximal one third of the root. This forms an area of relative hypovascularity, which predisposes lumbosacral roots to injury from compression.⁷ In addition, the small nerve fibers that transmit pain and parasympathetic function are more susceptible to mechanical compression than the larger nerve fibers that transmit motor, light touch, and proprioception.³ Unlike peripheral nerve fibers that have a more robust connective tissue covering, the

frail connective tissue that invests the lumbosacral roots provides little mechanical protection from compression. Other predisposing factors to CES and CMS include a congenitally narrow spinal canal or acquired spinal stenosis from degenerative changes.

The pathophysiologic mechanisms in development of CES may be related to direct mechanical compression, inflammation, venous congestion, or ischemia. Histologic examination of compressed nerve roots has shown dilatation of intradiscal veins with an inflammatory cell infiltrate.⁶ Sekiguchi et al.⁸ conducted a study showing endothelial cell dysfunction leading to contraction of blood vessels in nerves under chronic compression. Lee and Wolfe⁹ postulated that nerve root compression led to disruption of the blood-brain barrier and allowed antigenic proteins to enter the central nervous system. This in turn triggers an autoimmune inflammatory response leading to demyelination and degeneration. Rydevik et al.¹⁰ demonstrated mechanical compression of roots causing intraneural edema, resulting in increased intraneural pressure and decreased perfusion. One or more of these mechanisms are likely the cause of nerve root dysfunction in CES and CMS.

Bladder dysfunction is a hallmark of CES and CMS. The detrusor muscle of the bladder as well as the internal sphincter is controlled by the parasympathetic nerves that travel along the S2-S4 nerve roots. Parasympathetic innervation promotes bladder emptying by contracting the detrusor muscle and relaxing the internal sphincter. The external sphincter of the bladder, which is a striated muscle under voluntary control, is innervated by the pudendal nerve, which is also formed by fibers from the S2-S4 roots. Compression of the micturition center inside the conus medullaris or the roots causes loss of sensation to the bladder and subsequent inability to detect bladder fullness. In addition, loss of detrusor muscle and sphincter innervation causes inability to voluntarily empty the bladder and eventually leads to overflow incontinence.

Any compressive lesion can cause CES and CMS. The most common cause of CES is compression from central lumbar disc herniation at the L4-L5 or L5-S1 level.^{1,11,12} It may also be caused by spinal stenosis, epidural abscesses, neoplastic processes, traumatic injuries, infection, post-surgical hematomas, ankylosing spondylitis, lumbar punctures, chiropractic manipulation, and spinal or epidural anesthetics (Table 75.1).¹³⁻¹⁵ As mentioned previously, pure CMS can be caused by intradural tumors or vascular lesions, but is unlikely to be caused by extradural compression as this results in compression of the cauda

Table 75.1: Causes of cauda equina syndrome.

Degenerative	Disc herniation Spinal stenosis
Infectious	Epidural abscess
Hemorrhagic	Epidural hematoma Subdural hematoma
Trauma	Spinal surgery
iatrogenic	Spinal or epidural anesthesia Chiropractic manipulation
Tumor	Rheumatoid arthritis
inflammatory	Ankylosing spondylitis

equina as well. More commonly, CMS occurs as a mixed picture with CES when caused by extrinsic compression.²

HISTORY AND PHYSICAL EXAMINATION

Early diagnosis of cauda equina and CMS is crucial to prevent irreversible neurologic damage, but can be difficult. The initial signs and symptoms may be subtle and may evolve slowly over time. Symptoms such as urinary issues and sexual dysfunction are also easily attributed to other pathologies. In addition, the clinical symptoms may vary depending on level of pathology and number of nerve roots affected. Further complicating the diagnosis is the reluctance of patients to discuss certain findings such as erectile dysfunction or bowel and bladder incontinence, out of fear of embarrassment. Patients may frequently have insidious onset of symptoms or a long history of chronic back pain and may not be alarmed by their initial symptoms. The diagnosis is made on clinical grounds with radiologic studies used to define the type of compressive etiology, localize the level, and to assist in surgical planning.

Cauda equina syndrome has been described as having three classic patterns of presentation.^{5,16} It can present acutely as the first symptom of a herniated lumbar disc in a patient without previous history of back problems (type 1), acutely after a long history of chronic back pain and sciatica (type 2), or over a long period of time with slow progression of symptoms (type 3).

The aim of the initial history is to delineate the nature and chronicity of symptoms, possible etiologies as well

Table 75.2: Characteristics of conus medullaris and cauda equina syndromes.

	<i>Conus medullaris syndrome</i>	<i>Cauda equina syndrome</i>
Motor strength	<ul style="list-style-type: none"> No lower extremity weakness 	<ul style="list-style-type: none"> Level of compression <ul style="list-style-type: none"> <i>Pathology at L2 level:</i> Can affect all lumbosacral roots except L1 and result in motor weakness and decreased sensation below inguinal crease <i>Pathology at L4 level:</i> Preserved quadriceps strength and patellar reflexes with intact sensation down to L3 dermatome <i>Pathology at S2 level:</i> No lower extremity manifestation
Reflexes	<ul style="list-style-type: none"> Patellar and achilles reflexes unaffected Bulbocavernosus and anal wink reflex diminished 	<ul style="list-style-type: none"> Level of compression <ul style="list-style-type: none"> <i>Pathology at L2 level:</i> Decrease in all lower extremity reflexes <i>Pathology at L4 level:</i> Preserved patellar reflex with diminished Achilles reflex <i>Pathology at S2 level:</i> No lower extremity manifestations Any of the above level of compression can affect the downstream sacral roots and cause loss of anal wink and bulbocavernosus reflexes
Sphincter dysfunction	<ul style="list-style-type: none"> Atonic bladder Flaccid anal sphincter 	<ul style="list-style-type: none"> Atonic bladder Flaccid anal sphincter
Sensory	<ul style="list-style-type: none"> Perineal anesthesia 	<ul style="list-style-type: none"> Perineal anesthesia Loss of sensation in specific dermatomes of lower extremity depending on level of compression
Radicular pain	<ul style="list-style-type: none"> No radicular pain 	<ul style="list-style-type: none"> Symptoms dependent on level of compression

as bowel, bladder, and sexual function.⁶ Up to 62% of patients will report a recent history of trauma with the most common inciting events being weight-lifting, falls, or motor-vehicle accidents.^{12,17-19} Other risk factors include a history of cancer, infection, anticoagulation, and previous spinal surgeries. In most cases, the most common symptoms are back pain and radiculopathy.²⁰⁻²² This contributes to the difficulty in diagnosing CES as the majority of patients have had back pain or sciatica prior to presentation; however, in acute-onset CES, there is a sudden increase in the intensity of the back pain.

The manifestations of CES in the lower extremities will vary depending on the level of pathology. Pathology at the L2 level will affect all lumbosacral roots except L1. This can result in lower extremity weakness in all muscle groups as well as decreased sensation below the inguinal creases. In addition, it may cause a decrease in all lower extremity reflexes as well as urinary symptoms. Pathology at the L4 level will have preserved quadriceps strength, normal patellar reflexes, and intact sensation down to the L3 dermatome. With lesions affecting S2 and below, there

will be no lower extremity manifestations; however, there will be saddle anesthesia as well as urinary symptoms. This presentation is similar to CMS and clinically it is difficult to differentiate the two (Table 75.2).

The key to differentiating CES and CMS from an acute disc herniation or exacerbation of chronic pain lies in elucidating sacral nerve root dysfunction. The development of saddle anesthesia, bowel or bladder dysfunction, or sensorimotor deficits in the lower extremities should raise suspicion for these syndromes. Initial urinary irritative symptoms progress to altered urinary sensation and loss of a desire to void. With continued compression, there is a progression to painless urinary retention with overflow incontinence. Once compression has existed long enough to produce this level of dysfunction, the deficits are unlikely to recover despite decompression.^{3,23} Sexual dysfunction has been noted to be present in <5% of patients on presentation, but has been documented at around 30% in long-term follow-up. This difference may stem from patient's reluctance to disclose this at the time of presentation as well as the ease with which it can be attributed to

other causes.^{17,21,24} Sexual dysfunction can consist of erectile dysfunction, ejaculatory dysfunction, and decreased sensation during intercourse. Patients may be hesitant to volunteer such information and clinicians will need to specifically ask to elucidate these symptoms. Bowel dysfunction in patients may not always be evident as it ranges from lacking a sense of rectal fullness to frank inability to control defecation and is most often not as troubling to patients as their urinary symptoms.

Further adding to the diagnostic dilemma are documented cases of CES without complaints of bowel or bladder dysfunction. Urodynamic studies have shown patients can have disturbances in bladder function, which are subclinical.²⁵ The diagnosis in these cases was made on the basis of sexual dysfunction, saddle anesthesia, and bilateral lower extremity symptoms.^{13,26,27}

In terms of physical examination, a full neurologic examination, including perianal sensation and assessment of rectal tone, should be performed whenever CES or CMS is suspected. Sensory deficits most commonly occur over the perineal region, buttocks, and posterior thighs.²⁸ Seventy-six percent of patients presenting with CES will have decreased perianal sensation.²¹ Pinprick sensation should be tested in addition to light touch, as patients will often have intact light touch but diminished pinprick sensation.²⁹ This can be explained by proximity of the spinothalamic tracts to the autonomic tracts supplying the bladder. Complete perineal anesthesia to both light touch and pinprick at presentation has been shown to be a poor prognostic sign.³⁰ Motor deficits in CES can be of varying degrees from minor disturbances to paresis. Most commonly motor deficits are minimal if present at all.

With regard to reflexes, there is no consensus in the literature about pattern of reflexes in CES. Patients may have diminished or absent patellar or Achilles reflexes, but involvement is variable depending on the level of pathology. Compression of the conus medullaris should have no effect on lower extremity reflexes. Both CES and CMS can cause loss of bulbocavernosus reflex and anal wink reflex as these are sacral root mediated. The preservation of bulbocavernosus reflex is a good prognostic sign as it indicates an intact arc between pelvic afferents and sacral efferents.²

Once the diagnosis is established, an important clinical distinction is dividing CES into two stages of presentation as it affects both the urgency of management and

the prognosis. The first stage is incomplete cauda equina syndrome (CES-I), in which there are urinary symptoms such as altered sensation, poor stream, and loss of desire to void but no established retention. The second stage occurs as patients develop painless urinary retention and overflow incontinence (CES-R).³ Patients with established urinary retention at presentation have a much poorer prognosis than those who present with urinary issues but no established retention.

During patient evaluation, the differential diagnosis for presentations similar to CES and CMS should be kept in mind. This includes exacerbation of low back pain, lumbar disc herniation, peripheral neuropathy, diabetic neuropathy, acute inflammatory demyelinating polyneuropathy, neoplastic processes, traumatic injuries, and Guillain-Barre syndrome.

RADIOGRAPHIC EVALUATION

Radiologic investigations into CES and CMS can include plain radiography, myelography, computed tomography (CT), CT myelography, and magnetic resonance imaging (MRI). Plain X-rays are often the first study obtained for patients presenting with spine-related issues but are of limited value in evaluating CES. They can, however, reveal disc space narrowing suggestive of herniation, destructive changes due to neoplastic or infectious processes, as well as traumatic injury to the spinal column.

Plain myelography can be useful in identifying the site of compression, but shows far less detail than CT myelography and MRI. It is rarely used other than in resource poor settings where CT and MRI are unavailable.

Magnetic resonance imaging is the imaging modality of choice for assessing CES. It avoids the ionizing radiation of CT as well as the invasive nature of myelography. In addition, it can provide excellent resolution of any space-occupying lesions as well as delineate the degree of compression of neural structures.³¹

In patients unable to get an MRI, CT myelography is the imaging study of choice and can assist in identifying the site of compression. It has roughly equivalent sensitivity and specificity to MRI and can be performed in patients with pacemakers or other contraindications to MRI.³²

OTHER DIAGNOSTIC TESTS

The micturition center of the spinal cord is located at the S2-S4 levels. If the diagnosis is unclear, attempts at diagnosing detrusor dysfunction can be undertaken. Postvoid

residuals may be measured either with foley placement or bladder scans after voiding. Healthy volunteers have been noted to have <30 cc on postvoid residuals, whereas values of 100 cc or more are suspicious for urinary retention.³³

An additional diagnostic test that can be performed at the same time is the trigone sensitivity test. An inflated foley catheter is gently pulled and should produce the urge to urinate. Presence of trigone sensitivity may be used as an aid to differentiate between complete and incomplete CES.

Some authors have recommended preoperative urodynamic studies as a method of assessing detrusor activity and to assist in differentiation of CES-R and CES-I.^{34,35} These studies are also helpful in the postoperative period to document level of impairment. Obtaining these studies preoperatively can be done, but only if they will aid in the diagnosis and can be obtained expeditiously. Surgical decompression should never be delayed in an attempt to obtain urodynamic testing preoperatively.

SURGICAL MANAGEMENT

When a patient is diagnosed with CES or CMS and has a potentially reversible cause of compression, surgical decompression is the treatment of choice. The timing of surgical decompression remains the most important issue as well as one of the most controversial. It is not possible ethically to design a randomized study to examine early versus late decompression. In a retrospective review, Gleave and MacFarlane²³ concluded emergency decompression is only indicated in patients in the incomplete stage of CES (urinary symptoms but no established retention). It was noted that patients with established urinary retention and incontinence at presentation have poor clinical outcomes independent of time to surgery and require urgent but not emergent decompression so as to avoid trips to the operating room under less than ideal circumstances. Additional research has been done, which also supports this conclusion with regard to timing.^{21,36,37} However, some authors have advocated for emergent surgery with the reasoning that a damaging process to the neural elements should be addressed as soon as possible.^{16,38,39}

Ahn et al.¹² as part of a large meta-analysis looked at several factors including time from presentation to surgical decompression. Patients with preoperative rectal dysfunction or history of preoperative chronic low back pain were at an increased risk of continued postoperative urinary incontinence. The prognosis for rectal function after surgery worsened with a history of chronic low back pain.

In terms of time to decompression, the authors found increased risk of continuing urinary deficit, motor deficit, rectal dysfunction, and sensory deficit in the group decompressed at >48 hours as opposed to those who were decompressed earlier. They found no statistically significant difference between patients decompressed within 24 hours and those who were decompressed between 24 and 48 hours. Additionally, they found no difference in outcome with respect to resolution of pain, sensory and motor deficits, and urinary, rectal, and sexual dysfunction in patients who underwent decompression at >48 hours after symptom onset. They concluded that patients with CES/CMS should be decompressed within 48 hours, but that decompression within 24 hours showed no benefit. However, Kohles et al.⁴⁰ reviewed the statistics in this meta-analysis and concluded that due to small sample size and flawed methodology, they likely underestimated the value of early surgical decompression.

In a meta-analysis by Todd³⁹ looking at time from symptom onset to surgery with respect to resumption of socially normal bladder function, there was stronger evidence for the 24-hour rather than the 48-hour window for improving urologic outcomes.

In terms of operative planning, surgical treatment should be focused on alleviating the underlying compressive etiology. In general, the accepted surgical technique for treatment of CES or CMS is wide laminectomy, removal of the offending disk, hematoma or other space-occupying lesion as well as foraminotomies if needed for stenosis.^{17,20,36,40,41} Some authors have reported treatment through laminotomies, but this is currently not recommended as it requires additional traction on already compressed neural elements.⁶ Anterior decompression can be considered in the presence of vertebral body destruction from etiologies such as tumor or large abscess.

PROGNOSIS

The prognosis for CES and CMS depends on several factors including etiology, duration of symptoms, acuity of onset, number of spinal levels involved, and degree of neurologic deficit on presentation. The severity of bladder dysfunction at the time of surgery was a dominant factor in bladder function recovery in a study by Qureshi and Sell.³⁷ They performed a prospective longitudinal study that found a poorer prognosis for those patients with established urinary retention at presentation. Those with incomplete cauda equina at presentation had better urologic outcomes as well as significantly less likelihood of

back and leg pain at long-term follow-up. These results were supported by several other studies, which concluded the severity of bladder or anal sphincter disturbance at presentation were predictors of overall residual dysfunction after surgery.^{3,16,23,30,37,42} A study by Kennedy et al.,³⁰ did not find any predictive value in the severity of initial motor dysfunction, bilateral sciatica, or the level of injury. While there was a correlation between more rapid onset of symptoms and poorer outcomes, this finding did not reach statistical significance ($P = 0.052$).

No studies found a difference in prognosis with the level of herniation, but there has been evidence to suggest that involvement of the lower sacral nerve roots manifests with clinical symptoms, which are more subtle than cases that involve lumbar roots and are, therefore, more prone to delay in diagnoses.⁴³

With regard to overall recovery from CES, McCarthy et al.²¹ reviewed 56 cases and concluded patients do not return to normal status based on SF-36, Oswestry Disability Index (ODI), and Low Back Outcome Scores; however, subjective recovery of bladder and sexual function may continue for years following treatment of CES and has been attributed to the patient's ability to develop compensatory strategies.^{44,45} Approximately 75% of all CES cases eventually regain acceptable urologic function, but are frequently left with chronic back pain and lower limb as well as perineal sensory deficits.²³ The remaining percentage of CES patients will have poor outcomes and will need multidisciplinary treatment for ongoing urologic, bowel, and sexual dysfunction.

KEY POINTS

- Cauda equina syndrome and CMS are rare neurologic disorders that result from the dysfunction of sacral nerve roots in the vertebral canal, resulting in impairment of bladder, bowel, or sexual function.
- The most common cause of CES is compression from central lumbar disc herniation at the L4-L5 or L5-S1 level.
- A high index of suspicion is needed to diagnose CES and CMS. Symptoms such as urinary issues and sexual dysfunction are also easily attributed to other pathologies. Patients may frequently have insidious onset or a long history of chronic back pain and may not be alarmed by their initial symptoms.
- Magnetic resonance imaging is the imaging modality of choice to delineate a compressive lesion.

Computed tomography myelography can be performed in those who have contraindications to MRI.

- In patients with incomplete CES (urinary symptoms, but no established urinary retention), surgical decompression should be undertaken as soon as safely possible and at least within 24 hours. No data exist to elucidate the difference between emergent decompression and those which occur within 24 hours. However, in the absence of further data, emergent decompression should be considered as soon as adequately skilled personnel and infrastructure are available, with the goal being to prevent progression to established urinary retention. Those with established urinary retention at presentation require urgent, but not emergent decompression.

Ahn UM, Ahn NU, Buchowski JM, et al. Cauda equina syndrome secondary to lumbar disc herniation: a meta-analysis of surgical outcomes. *Spine (Phila Pa 1976)*. 2000; 25(12):1515-22.

Large meta-analysis that looked at several factors including time from presentation to surgical decompression. The authors found increased risk of continuing urinary deficit, motor deficit, rectal dysfunction, and sensory deficit in the group decompressed at >48 hours as opposed to those who were decompressed earlier. They found no difference between the 0-24-hour group and the 24-48-hour group. Additionally, they found no difference in outcome in any groups decompressed after 48 hours. They concluded that patients with CES/CMS should be decompressed within 48 hours, but that decompression within 24 hours showed no benefit.

Gleave JR, MacFarlane R. Prognosis for recovery of bladder function following lumbar central disc prolapse. *Br J Neurosurg*. 1990;4(3):205-9.

In a retrospective review, Gleave and MacFarlane noted that patients with established urinary retention and incontinence at presentation have poor clinical outcomes independent of time to surgery. Therefore, those with established retention at presentation require urgent but not emergent decompression so as to avoid trips to the operating room under less than ideal circumstances. Emergent decompression should only be considered in patients with incomplete cauda equina syndrome (urinary symptoms, but no established urinary retention).

Kennedy JG, Soffe KE, McGrath A, et al. Predictors of outcome in cauda equina syndrome. *Eur Spine J*. 1999;8(4): 317-22. Retrospective review of predictors of outcomes in cauda equina syndrome. The authors found no predictive value in the severity of initial motor dysfunction, bilateral sciatica, or the level of injury. They did find a correlation between more rapid onset of symptoms and poorer outcomes, but this did not reach statistical significance ($P = 0.052$). Similar to other studies, they found that the severity of bladder dysfunction at time of presentation was a predictive factor for postoperative bladder function.

Qureshi A, Sell P. Cauda equina syndrome treated by surgical decompression: the influence of timing on surgical outcome. *Eur Spine J*. 2007;16(12):2143-51.

Prospective longitudinal study that found poorer prognosis for patients with established urinary retention at presentation. Those with incomplete cauda equina at presentation had better urologic outcomes as well as significantly less likelihood of back and leg pain at long-term follow-up. Thus, the severity of bladder dysfunction at the time of surgery was the dominant factor in bladder function recovery as well as long-term back and leg pain.

Todd NV. Cauda equina syndrome: the timing of surgery probably does influence outcome. *Br J Neurosurg*. 2005; 19(4):301-6; discussion 7-8.

Meta-analysis of cauda equina syndrome cases looking at time from symptom onset to surgery with respect to resumption of socially normal bladder function. The authors found stronger evidence for decompression within the 24-hour rather than the 48-hour window in order to improve urologic outcomes.

Lumbar Nucleus Pulposus Replacement

- » Disc Replacement Strategies

INTRODUCTION

Low back pain (LBP) remains an extremely common entity, affecting approximately 85% of adults during their lifetimes.¹ As many as 40% of this group² are believed to have pain generated by abnormalities attributable to the intervertebral disc. While the proportion of patients requiring surgical intervention for the treatment of so-called degenerative disc disease (DDD) is low, nonsurgical methods can be ineffective, procedural options are limited, and outcomes remain unpredictable.

Disc degeneration results from a complex pathophysiologic cascade likely triggered by an acute injury or insult to the disc-endplate complex. The consequences are impaired diffusion and transport of key nutrients to the nucleus pulposus (NP), followed by its degeneration and dysfunction.³ The nuclear environment cannot be maintained by the production of adequate proteoglycans and noncollagenous proteins, and the nucleus fails both biochemically and mechanically. The NP also improperly interacts with the annulus fibrosus, causing painful annulus degeneration, disc collapse, reactive bony changes, osteophyte development, increased stress on adjacent joints, instability, and potentially both cord and nerve root compression.

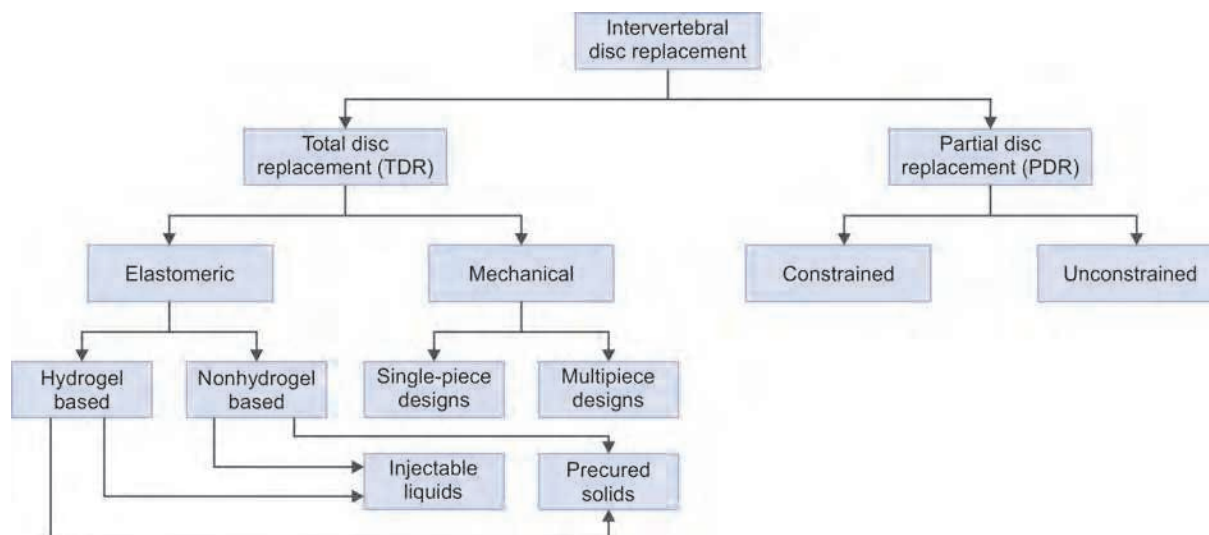

The current standard of care for painful disc degeneration is conservative, with the utilization of nonsteroidal anti-inflammatory drugs, physiotherapy, chiropractic care, and occasionally pain management if a particular “pain

generator” can be identified. From a surgical perspective, options are limited in scope and questionable in terms of effectiveness, and include discectomy and fusion, discectomy and arthroplasty, or derivations of the above. Unfortunately, these options cannot fully address the underlying dysfunction of the nucleus, restore its function, or halt the progression of the degenerative cascade.

Lumbar NP replacement or partial disc replacement (PDR) is a procedure in which the diseased NP is exchanged with a synthetic implant in an attempt to address pain, maintain motion, restore functional loading capacity, and restore the physical parameters of the NP. Unlike total disc replacements (TDRs), PDRs are intended to replace the NP with preservation of the annular, cartilaginous, and bony endplate components of the disc. The potential benefits of PDR over fusion include the restoration of physiologic or near-physiologic motion, the reduction of stresses on adjacent segments, and the avoidance of fusion-related challenges with regard to the consequences to adjacent segment, osseous union, graft harvesting, and/or controversial orthobiologics.

ANATOMY AND PHYSIOLOGY OF THE NORMAL INTERVERTEBRAL DISC

The intervertebral disc is composed of the peripheral annulus fibrosus, the central NP, and the surrounding cartilaginous endplates. The annulus fibrosus is a thick fibrous

Flowchart 76.1: Taxonomy of disc replacement strategies.

Source: Adapted from Coric D, Mummaneni PV. "Classification of nucleus replacement devices" in nucleus replacement technologies: invited submission from the Joint Section Meeting on Disorders of the Spine and Peripheral Nerves. *J Neurosurg Spine*. 2008;8:115-20.

band consisting of predominantly type I collagen that functions to effectively contain the more gelatinous nucleus within the intervertebral space (Flowchart 76.1). The border between the annulus and nucleus does not exist as a distinct boundary, but has a gradual transition. Fibrous bands of the annulus predominate at the periphery of the disc, but the composition becomes more semi-solid toward the center.³

The NP is composed of type II collagen, mucopolysaccharides, and glycosaminoglycans. The hydrophilic proteoglycans provide a strong osmotic gradient that is able to absorb and sequester water. The nucleus optimally flexes and interacts with the surrounding annulus fibrosis in its hydrated state. These two essential properties define the challenges of effective nucleus replacement.

The vertebral endplate is composed of a thin layer of hyaline cartilage and the underlying bony endplate. The hyaline cartilage, predominantly also type II collagen, serves to maintain the disc metabolism by restricting water and proteoglycan exit from the nucleus while permitting the passage of small molecules through diffusion and fluid flow. Diffusion flows follow concentration gradients and allow the passage of molecules like glucose and oxygen. Fluid flow and the passage of larger molecules such as proteins are assisted by mechanical loading.⁴

Biomechanically, the nucleus serves as a fluid "cushion," which both resists and transfers compressive forces to the endplates and encompassing annulus. The annulus, by

contrast, resists tensile, torsional, and radial (hydrostatic) forces as they are applied under loading conditions. Under spinal compression, the generated hydrostatic pressure within the NP is restrained by the hoop stress tolerated by the annulus. Healthy discs exhibit viscoelastic properties, meaning they undergo both elastic changes and time-dependent changes depending on the applied load. Synthetic nucleus replacements, then, must be stiff and viscous enough to withstand compressive forces without migrating or extruding, yet compliant enough to expand radially under pressure, thus dissipating loads between the endplates and the preserved annulus.³

PATHOPHYSIOLOGY AND NATURAL HISTORY OF THE DEGENERATING INTERVERTEBRAL DISC

There is an appreciable difference in the water content of the intervertebral disc that occurs with aging. In the young, water comprises up to 80% of the NP. With normal aging, this declines secondarily to a gradual change in the production of hydrophilic proteoglycans. Additionally, nutritional transport decreases along with the concentrations of large aggregated proteoglycans, the absolute number of viable cells, and pH. Concurrently, there is an increase in small nonaggregated (i.e. less hydrophilic) proteoglycans, concentrations of keratan sulfate, lactic acid, and degradative enzyme activity.⁵

Although the absolute quantity of collagen does not significantly change with degeneration, conversion of relatively hydrophilic type II collagen-based cartilages to fibrocartilage occurs. The NP becomes more fibrous in nature and loses significant osmotic potential.⁶ Histologic degenerative changes are apparent as early as the third decade of life. As the NP dehydrates, it loses its gelatinous consistency and decreases in volume—these changes are manifested as the generalized loss of height with aging, beginning, on average, in the fifth decade of life.

In addition to changing its shape and size, dehydration of the NP alters its biomechanics. The desiccated disc can no longer transfer radial forces to the annulus. Under compressive loads, the otherwise healthy annulus buckles, with its peripheral fibers bulging outward and its inner fibers folding inward. With repetitive cycles, this aberrant motion causes splitting, tearing, and weakening of the annulus. As annular tears propagate, not only does the risk of NP herniation escalate, but also essential fluids and nutrients escape from the formerly enclosed disc space.⁶ The pumping mechanism by which the disc receives nutrients is lost along with its regenerative potential. Finally, because the nociceptive nerve fibers innervating the disc are located within the outer third of the annulus, this process may cause significant and chronic discomfort. Liberated nutrients, metabolites, and inflammatory mediators irritate the peripheral innervation of the annulus.

The degenerated disc decreases in height and becomes intrinsically more rigid and less pliant. This culminates in a mechanical decrease in motion, which, in turn, is exacerbated by subjective pains with motion and/or adjacent muscular spasms. The ultimate result is progressive autofusion across the collapsed intervertebral space, with total loss of motion between the vertebral bodies and, eventually, their facets.⁷ Additional degenerative processes may be triggered in adjacent structures, including facet degeneration, facet hypertrophy, osteophyte formation, and thickening/buckling of the posterior ligaments. If these dysplastic secondary changes result in tissue encroachment into the spinal canal, the lateral recesses, or the neural foraminae, it may result in concomitant lumbar stenosis.

■ DISC REPLACEMENT STRATEGIES

Disc replacement strategies are rapidly evolving and feature a variety of designs and material compositions. Regardless of design specifics, however, the major goals of disc replacement are (1) to eliminate the painful dysplastic elements of

the joint, (2) to preserve the natural range of spinal motion and function, and (3) to reduce mechanical stresses on adjacent segments, theoretically reducing, if not eliminating, adjacent segment degeneration and/or disease.

Disc replacement strategies may be divided into TDR and PDR, also known as nucleus replacement. Total disc replacements aim to replicate the combined function of the annulus and NP, and, for the most part, the endplate as well, while PDRs are annulus-sparing. Flowchart 76.1 displays the array of disc replacement strategies organized by function and composition.

Partial Disc Replacement

The hydrated, semi-solid NP functions to distribute compressive forces cranially and caudally to the endplates, and radially to the annulus. Under axial loading conditions, the disc effectively converts compressive forces into the tensile forces conferred on the outward-bulging annulus. In biomechanical experimental models in which the NP has been removed, axial loads lead to buckling of the annulus, with the outer layers bulging outward and the inner layers caving inward.⁸ Additionally, load is shifted posteriorly, causing the facets to bear supraphysiologic loads. Providing a substitute for the damaged or absent NP may therefore restore the natural kinematics of the normal functional spinal unit (FSU), preventing further damage to the annulus and relieving strains on the posterior facets.

Partial disc replacement poses an attractive potential surgical option for relatively young, healthy patients with symptomatic single-level early DDD. While current surgical standards such as fusion or even TDR might prove overly invasive solutions, PDRs function to replace only the diseased nucleus and may serve to preserve both the intact annulus and the motion segment.⁹ Additionally, PDR can theoretically be performed with minimally invasive or percutaneous techniques and through a greater variety of surgical approaches than TDRs, including anterior transperitoneal, retroperitoneal, lateral, trans-sacral, and/or posterior approaches, depending on the device. Many proponents advocate PDR as a revision option for postpartial discectomy patients with recalcitrant radiculopathy;¹⁰ and some PDR implants are being used to augment primary discectomy techniques.

Partial disc replacement designs in development encompass a broad variety of design philosophies, accounting for at least 25 unique devices in preclinical or clinical testing as of 2007.¹¹ Partial disc replacement strategies can be functionally divided into two groups: elastomeric and mechanical.

Elastomeric devices generally attempt to replicate the natural function of the NP. Mechanical devices side-step attempts to reproduce the material properties of the native disc and instead employ stiffer, more durable materials to maintain both motion and the height of the disc space.

Along with the mechanical properties of any PDR implant, the geometry of the implanted nucleus also plays an essential role in its potential effectiveness. In human cadaver studies, Joshi et al. demonstrated that variations in the shape and volume of the implant influenced the stiffness of the FSU to a greater degree than the implant modulus of elasticity.⁹ Modifications to implant height and diameter were more influential over FSU stiffness than changing the implant modulus by over two orders of magnitude. This suggests that the geometry of the implant, especially its final diameter, plays an essential role in promoting optimal annulus function in vivo.¹² Several finite element analyses have confirmed the restoration of compressive biomechanics of PDS and suggested even that a larger volume implant, even an “overfilled implant,” more accurately restores the compressive biomechanics of the NP.^{13,14}

Table 76.1 summarizes some of the major PDRs under development with reference to their design, composition, material properties, containment, manufacturer, stage of development, and respective potential advantages and disadvantages. While many are still in preclinical development, most of those included have passed various European and/or Asian government standards for investigative use. Several products have obtained US Food and Drug Administration (FDA) approval under the Investigational Device Exemption (IDE), meaning they can be used in a limited number of patients to assess the safety and efficacy of the premarket product.¹⁵

Elastomeric PDR Devices

Elastomeric PDR devices are NP substitutes composed of a wide variety of viscoelastic materials. Elastomeric PDRs aim to recreate the functions of the healthy NP with regard to the interaction with the annulus, the dissipation of stress, and absorption of axial compressive load. Materially, elastomeric devices can be divided into hydrogels (materials with strongly hydrophilic properties) and nonhydrogels. Both hydrogel and nonhydrogel derivatives are available as injectable liquids and precured solids. Finally, elastomeric PDRs may be contained or uncontained, defined here as the presence or absence of an outer volume-limiting casing.

The major challenge for elastomeric PDRs is to provide a device that adequately mimics the mechanical properties of the native NP. Insufficiently stiff implants may lead to an underconstrained motion segment that increases stress on the adjacent discs and, potentially, unwittingly fosters degeneration. Conversely, an excessively stiff material may lead to implant subsidence through the endplate and thus failure of the motion segment.¹⁶

There are two main mechanical properties that require consideration for NP-replicating devices: the modulus of the device (slope of its stress-strain curve through its elastic region) and its corresponding Poisson's ratio. Poisson's ratio quantifies the horizontal expansion of a material under vertical stress, and is expressed as the ratio of lateral strain to axial strain and is unitless. Healthy human NPs have been determined to possess an approximate modulus (the stiffness of a material at equilibrium with surrounding fluid) of a healthy human NP has been shown to equal 1.01 ± 0.43 MPa¹⁷ with a Poisson's ratio of 0.62.¹⁸

Among the criticisms of elastomeric devices is the relative potential for fatigue failure when compared to intrinsically more durable metal implants.¹⁹ Yet, despite the still infantile nature of elastomeric clinical testing, we are not aware of a study that has demonstrated fatigue-related changes to the implant, detrimental or otherwise. Several elastomeric devices have been validated in in vitro loading for up to 50 million cycles without evidence of functional compromise.⁸ Long-term clinical data is needed before the true longevity of these devices is evaluated.

Hydrogel Elastomeric PDRs

Hydrogels are synthetic, hydrophilic polymers that absorb various quantities of water inversely proportional to the applied pressure.⁸ Several synthetic hydrogels have been found to have material and water-imbibing properties near equal to those of the healthy NP. The NeuDisc (Replication Medical, Inc, Cranbury, NJ) is a preformed solid hydrogel made from acrylic copolymers and contained by Dacron (polyethylene terephthalate) mesh. Acrylic hydrogels have been confirmed in cadaver motion segment testing to have compressive moduli between 0.55 and 4.28 MPa, depending on the applied load.²⁰ Pilot clinical trials are apparently ongoing.

Nonhydrogel Elastomeric PDRs

NuCore (Spine Wave, Shelton, CT) is a protein polymer synthesized by bacteria via recombinant DNA. This inject-

able substrate has a protein concentration (19%), water content (79%), and various mechanical properties similar to that of the natural disc.²¹ The device is not contained and thus depends on an intact annulus with a minimal annulotomy for implantation.³ NuCore is the first injectable liquid PDR to receive approval by the US FDA under IDE. It is currently being evaluated in the preclinical setting as an adjunct in primary discectomy procedures for subacute disc herniation and for the treatment of DDD.¹⁰

Newcleus (Zimmer Spine, Minneapolis, MN) is also an uncontained device made from polycarbonate urethane. Unlike the other nonhydrogel elastomeric PDRs discussed here, Newcleus is a relatively stiff spacer that coils into its “memorized” spiral shape upon implantation. The implant possesses the unique ability to find its own orientation and position once implanted and thus may not demand the same level of precise intraoperative positioning as required by other precured PDRs and TDRs. Newcleus is apparently under preclinical testing in Europe.

Injectable Liquid Elastomeric PDRs

Hydrogel PDRs can be further divided by their preimplantation form. Products are either initially precured during manufacturing and implanted in a preformed semi-solid

state, or they are manufactured as injectable liquids that solidify in situ. Perhaps the most obvious advantage of the latter is that liquids may be amenable to implantation through a smaller annulotomy and via a variety of minimally invasive approaches. Minimizing the size of the annulotomy may decrease the risk of implant migration following in situ hardening.

Examples of injectable PDRs in development include Biodisc (Cryolife, Kennesaw, GA), an albumin/glutaraldehyde-based hydrogel that cures in situ and DASCOR (Disc Dynamics, Inc, Eden Prairie, MN; Fig. 76.2), a polyurethane-based liquid nonhydrogel. In the DASCOR system, a flexible polyurethane preformed balloon is inserted via small annulotomy into the disc space and filled via catheter with freshly prepared liquid polyurethane until the desirable fill is achieved (Figs. 76.1A and B).²¹ Implanted polyurethane, such as that found in the DASCOR, has been determined to have an elastic modulus ranging from 3.3 to 5.4 MPa, depending on the applied load,¹⁶ and a Poisson’s ratio of 0.48.²² These properties closely resemble those of the native disc. Two-year outcomes for two European multicenter, nonrandomized DASCOR implants in 85 patients demonstrated significant improvement in disability scores, pain scores, and narcotic dependence. No extrusion of devices was noted and only minimal subsidence was noted in two patients.²¹

Precured Solid Elastomeric PDRs

Precured solid elastomeric devices are preformed implants that are configured to have viscoelastic properties similar to those of the native disc. These are available in both hydrogel and nonhydrogel forms. The major concern with preformed solid elastomeric devices over the course of their history is the potential for extrusion following implantation. This occurs in part because a relatively larger annulotomy is required for implant insertion, which raises the risk of containment failure and device extrusion. Despite these shortcomings, solid elastomeric PDRs are some of the most extensively studied and implanted devices in development.

The Prosthetic Disc Nucleus (PDN; Raymedica, Inc, Bloomington, MN; Fig. 76.2) is the most frequently implanted and most extensively studied PDR to date. Since the original pilot studies in 1996, over 5,500 PDN devices have been implanted.¹⁰ The PDN is composed of a polyacrylonitrile/polyacrylamide core contained in a polyethylene jacket. The jacket is designed to prevent hydrophilic overexpansion in the disc space. Early models of the PDN suffered from problems with implant migration and subsidence, which are thought to have been at least partially addressed through design alterations. This may be second-

dary to the trapezoidal reshaping of the implant, with anterior and posterior wedges that assist in the maintenance of its intervertebral position, as well as modification of its water-imbibing potentials.^{8,19} Although available data from clinical trials indicates good pain relief, improved functionality, and better maintenance disc height in the majority of patients, approximately 10% of these devices have been explanted for migration since their inception.¹⁹

Mechanical PDR Devices

Mechanical PDR devices are designed to maintain the disc space, and are less concerned with replicating the viscoelasticity and annular/endplate interactions when compared with elastomeric PDRs. While mechanical implants are less prone to issues of fatigue, biocompatibility, and potential extrusion or leakage following implantation, they possess some disadvantages, including a relative inability to absorb load, an elevated risk of subsidence, and an inability to evenly disseminate forces across the endplates and annulus.¹⁰

Single-Piece Mechanical PDRs

Several modern single-piece devices are currently under investigation.²³ Regain (Biomet/EBI Medical, Parsippany, NJ) is a disc-shaped biconvex implant with a graphite core and pyrolytic carbon coating (Fig. 76.3). Regain is fashioned from geometric profiles developed via elaborate motion-tracking techniques.⁸ The result is a smooth disc that is designed to conform to the natural concavities of the vertebral endplates. It is available in several geometric anatomic and pathologic (i.e. lordotic) profiles.¹⁹ Similar mechanical interbody spacers under investigation include those composed of polyether ether ketone (PEEK) and cobalt chromium. Clinical data is limited at this time, but clinical trials are thought to be ongoing in Asia.

Multipiece Mechanical PDRs

Partial disc replacement designs employing two or more individual components generally provide an artificial moving articulation between the implant surfaces. This introduces two major design considerations: first, the biomechanics of the artificial articulation and second, the wear profile of the components and potential issues with particle debris. Like TDRs, motion-bearing PDRs can be defined as constrained or unconstrained. Constrained technically refers to the limitation of one or more degrees of freedom (DOF). Several forms of TDR are dual-axis and

do permit translation; in these systems, posterior elements such as the facets serve as a block against excessive translation. In these unconstrained systems, supraphysiologic translation may pose risks of increased facet loading and degeneration, or so-called ‘same-segment disease.’²⁴

The NuBac PDR (Pioneer Surgical Technology, Inc, Austin, TX) is a two-piece mechanical PDR consisting of a ball-and-socket joint. It is a constrained device, allowing three degrees of rotational freedom without translation. NuBac features a large surface area that may distribute compressive forces more evenly.¹⁰ It is composed of polyether ether ketone (PEEK), a semicrystalline polymer with high mechanical strength, resistance to wear, and notable biological inertness. Further, its relatively elastic composition is theorized to increase its ability to dissipate compressive forces and therefore decrease risk of subsidence.²⁵ Wear particle debris has been shown to be roughly comparable with other arthroplasties.²⁶ Although preliminary results are encouraging, long-term data from clinical trials is pending.²⁷

The modular Intervertebral Prosthetic Disc (IPD; Dynamic Spine, Inc, San Diego, CA) is a multipiece mechanical PDR, notable for its unconstrained mechanics and potentially annulus-preserving design. The device consists of coiled spring(s) between cobalt-chromium or titanium plates that are embedded and fixed deep within the vertebral bodies (Fig. 76.4). Its spring system permits rotation, as well as translation in axial, coronal, and sagittal

Fig. 76.4: Lateral radiographs of a mechanical multipiece partial nucleus replacement, the Modular Intervertebral Prosthetic Disc (Dynamic Spine, Inc, San Diego, CA). The device pictured is being tested in cadaver vertebrae and is shown in flexion (right) and extension-loaded (left) states. Note that the long screws are not part of the design but are used to hold the vertebrae during pre-clinical testing.

planes. With six DOF, the device has the potential, at least theoretically, to better replicate the normal motions of the spine. Furthermore, its modular spring system may allow adjustment of its mechanical properties to better replicate native disc function. Implantation of the device is performed through vertebral bone window(s) and thus leaves the degeneration-prone annulus completely intact.¹² Such potential benefits, however, must be weighed against the morbidities of its relative invasive implantation, given the exposure required for multiple osteotomies, as well as the potentially added risks of iatrogenic injury, postoperative instability, and bone nonunion. The IPD, still in preclinical development, has been inserted successfully into living bovine subjects using various anterior, anterolateral, or direct lateral approaches. Clear benefits of total-annulus preservation in PDRs have yet to be demonstrated.

Operative Indications for Partial Disc (Nucleus) Replacement

Relative indications for disc arthroplasty have included severe, unremitting, and localized lumbar pain at a single

level, 6 months or greater in duration.²⁸ Symptoms must be demonstrated to result from a single, specific degenerated intervertebral space. Facet degeneration and other pathology at that motion segment must be absent and the remaining disc space must be at least 5 mm in height.¹⁰ Positive magnetic resonance imaging (MRI) findings in the setting of LBP do not provide sufficient or reliable indications for arthroplasty. Thus, despite its many controversies, correlative positive discography is considered by many to be a preoperative requirement, as are MRI-visualized Modic changes, consistent with the isolated symptomatic level.

The development of PDR technologies may soon herald a change in indications. Young, healthy patients with single-level early NP degeneration and otherwise healthy spines may benefit from the annulus-preserving potentials of elastomeric PDRs. Such implants might theoretically restore motion, alleviate pain, and actually avoid further degeneration both at the operative and adjacent levels. Additional broader indications proposed for PDRs include otherwise well-preserved discs with recurrent radiculopathy after previous discectomy, or, as discussed, the substitution of diseased nucleus with injectable elastomers during primary discectomy procedures.

Contraindications to Disc Replacement

Absolute Contraindications

Contraindications to TDR/PDR have traditionally been felt to be quite common.²⁹ Absolute contraindications include nondiscogenic pain, lumbar stenosis, active infection or malignancy, skeletal immaturity, morbid obesity [BMI (body mass index) ≥ 40], and known nickel or similar metal allergies. Bilateral spondylolysis, spondylolisthesis, or defects of the posterior elements are also absolute contraindications to PDR. Finally, morbid obesity is contraindicated due to the increased stresses placed across the disc space and the elevated risk of subsidence.

Relative Contraindications

Osteoporosis and osteopenia (T score ≤ -1.0), nonmorbid obesity (BMI 30–40), and the various psychological pathologies comprise common relative contraindications for nucleus replacement. Scoliosis is a debated contraindication, but concern for early loosening and failure exists if devices are placed asymmetrically.

Certain contraindications may exist in relation to the planned surgical approach for the device implantation. Prior intraperitoneal abdominal procedures may have resulted in adhesions that preclude transperitoneal access approach. Some authors warn that prior retroperitoneal procedures are an absolute contraindication to any type of anterior approach, given the potential scarring of, and thus an inability to adequately mobilize, the great vessels.²⁸

Surgical Techniques and Approaches

Total disc replacements and mechanical PDRs are typically performed via an anterior transperitoneal or an anterolateral retroperitoneal approach. Such procedures generally require an anterior approach for direct access to the complete disc space and/or vertebral bodies. Elastomeric PDRs, especially injectable liquid forms, are generally amenable to greater variety of approaches. Like TDRs, specific techniques for implantation vary highly between devices, but share several basic steps, including positioning and approach, annulotomy, removal of the nucleus and endplate preparation, device implantation, and closure.

CONCLUSION

Symptomatic disc degeneration is a common source of LBP and may begin as early as the third decade. Despite its commonality, the diagnosis and management of discogenic pain remains a challenge. Given the nonspecific nature of its clinical presentation and its variable imaging findings, many consider the diagnosis to be one of exclusion. Fortunately, over 90% of patients with nonspecific LBP will typically experience complete resolution of symptoms using conservative measures alone.

For the minority of patients with refractory symptoms, surgical intervention may be indicated. Traditionally, arthrodesis has been the sole surgical treatment option, but its efficacy in this patient population remains poor. Lumbar total disc and nucleus replacement may present attractive alternatives because of their theoretical abilities to eliminate pain, prevent or slow adjacent segment disease, and restore the natural kinematics of the spine. Total disc replacement has been performed for over 20 years internationally with varying success rates, and has shown equivalence to fusion for symptomatic patients in some FDA trials.

Partial disc replacement, a type of arthroplasty that replaces the NP but spares the annulus portions of the

disc, is in its infancy. At this time of publication, no devices are cleared for routine use. However, investigational trials, both domestically and internationally, have demonstrated some preliminary success. Partial disc replacements have the potential to combine the motion-sparing benefits of TDRs with the ability to preemptively treat the source of early-stage disc degeneration, the nucleus. Early restoration of nuclear function is thought to promote healthy interaction with the annulus and the surrounding endplates, and potentially halt the degenerative cascade.

KEY POINTS

- Discogenic pain is a common source of lumbago; 90% of cases will resolve with nonoperative measures alone.
- Symptomatic disc degeneration is a diagnosis of exclusion.
- Fusion remains the standard surgical treatment for discogenic pain despite controversial indications and poor outcomes in this population.
- In select patients, lumbar disc arthroplasty may be an effective alternative to fusion. Precise indications include isolated, single-level, degenerative disc disease with an absence of facet, or adjacent degenerative processes. Symptoms must be refractory to nonoperative measures and 6 months or longer in duration.
- Partial disc arthroplasty may be indicated for patients with isolated disease of the nucleus pulposus. Many of the proposed techniques may be performed in a minimally invasive manner and have the theoretical potential to eliminate axial pain, restore disc height and motion, and protect the surrounding annulus from further degeneration.
- At the time of publication, all partial disc replacement devices are for investigational use only.

- » Clinical Assessment and Diagnosis

- » Case Example

ANNULAR PATHOLOGY AS THE TARGET OF THERAPY

According to a cadaver study conducted by Kirkaldy-Willis in the 1970s, the disc undergoes degenerative changes involving a cascade of events leading to reduced segmental stability followed by a natural stiffening of the segment.¹ Early changes, namely annular tears, are often neglected which leads to a limit of the understanding of symptom generation, an overemphasis on imaging, and inadequate treatment plans. Kirkaldy-Willis has since elaborated on nerve root and pain generation noting that a degenerative disc may present with back pain, sciatica, and claudication without impinging on nerve roots.² Although surgeons have historically managed symptoms of neural compression or spinal instability, they traditionally have not addressed early annular pathology. Recently, there has been a growing interest in addressing annular defects earlier on to address symptoms and limit the progression of the degenerative process. Utilizing various technologies through a transforaminal endoscopic approach under local anesthesia has allowed surgeon to better understand and address annular disease. A typical case is shown in Figure 77.1 where a posterolateral annular tear resulting in a herniated can be seen in a patient complaining of severe low back and leg pain.

Structure and Function

Intervertebral discs are composed of two primary structures: an outer annulus fibrosus that surrounds an inner

nucleus pulposus.³ The annulus fibrosus is well-organized into a series of concentric laminar fibrous rings. The rings are separated by interlamellar septae which contain an adhesive complex made of proteoglycans. The cohesiveness between the rings allows them to work in unison while dynamic loading forces are applied. The annulus is made of type I collagen, proteoglycans, water, and fibroblast-like cells. The collagen fibrils resist tensile and distraction forces, while the fibroblast-like cells are responsible for making type I collagen and proteoglycans. In addition, the annulus fibrosus can be further divided into an inner and outer portion based on structural differences. The inner annulus

Fig. 77.1: MRI of L5-S1 intervertebral disc with a posterior annular tear with associated degenerative changes, but no cord compression in patient who presented with back and leg pain.

fibrosus is a transition zone between the outer annulus and the central nucleus pulposus. The inner annulus contains an extracellular matrix that is a hybrid of both: containing less organized, compact rings than the outer annulus, but remaining less hydrated than the nucleus pulposus. The nucleus pulposus is made of type II collagen, proteoglycan, water, and chondrocyte-like cells. It is able to resist compression well due to the higher proteoglycan and water content. The viscoelastic matrix helps to equally distribute forces and the chondrocyte-like cells make type II collagen and proteoglycans. The intervertebral disc is avascular with most of its nutrition reaching the nucleus pulposus through diffusion. The sinuvertebral nerve which arises from the dorsal root ganglion innervates only the superficial fibers of the annulus. However, an ingrowth of nerve fibers into deeper layers of the annulus has been observed in degenerative disc.⁴

Types of Annular Tears

There are three main types of annular tears: peripheral, concentric, and radial (Fig. 77.2). A peripheral tear, also known as a rim tear, involves the most peripheral lamellae of the annulus. A concentric tear is circumferential and splits between the lamellae of the disc. Both peripheral and concentric tears tend to occur as a result of an acute traumatic event, such as during sporting activities. However, radial tears, which progress from the innermost part of the annulus to the outer margins, are commonly a result of degenerative changes. Tears near the junction between the cranial endplate and annulus lead to an upward migration of herniated nuclear fragments as opposed to a downward migration when the tear is closer to the caudal endplate. The propagation of annular tears can result in extrusion of the nucleus pulposus into the annulus with

concomitant leakage of proteins and cytokines into the disc space and surrounding soft tissues and nerves.

Hypothesis of Symptom Generation

It is thought that symptoms from an annular tear emanate from the ingrowth of vascular tissue and nerve endings into the annulus with the associated presence of inflammatory cytokines and chemokines that are produced by the degenerating intervertebral disc (IVD). When exploring the annular tear surgically in a patient with severe back pain, it is common for the surgeon to encounter incarcerated fragments of the nucleus pulposus with the inflamed annular tissue. It has been hypothesized that these fragments may prevent healing of the defect and lead to chronic pain and disability.⁵

Pathophysiology

Following an annular tear, there is an ingrowth of vascular tissue and dense nerve fibers into the annulus, which become inflamed from the release of cytokines.⁴ The annulus has poor intrinsic healing capability which is further limited by the entrapped nucleus pulposus fragments. The tear is unable to seal off due to the herniated fragments, resulting in persistent leakage of cytokines.⁵ Other pathological changes also occur during aging. The number of layers in the annulus decrease with age, which is compensated by an increase in thickness of the remaining layers.⁶

Neurologic symptoms and pain associated with an annular tear are mediated mostly by cytokines and a cascade of inflammatory changes as opposed to mechanical compression associated with a herniated disc.^{7,8} The cytokines induce an up regulation in sodium channels in nerve endings which play a role in radiculopathy and can be blocked with local anesthetics that target

Fig. 77.2: The three types of annular tears are peripheral, circumferential, and radial tears (left to right).

peripheral sodium channels.^{9,10} This is further supported by the mitigation of nucleus pulposus-induced effects on nerve conduction velocity by cytokine inhibitors.¹¹

The normal intervertebral disc is poorly innervated with nociceptive nerve fibers only penetrating a few millimeters into the annulus. However, with degenerative changes the annulus becomes more friable and cytokines induce vascular and neural growth. Substance P and other cytokines have also been found extensively in nerve fibers along the margins of the annulus.^{12,13} Neurotrophins, which induce neural genesis, survival, and development, also play a role in the symptomatology of annular tears. Neurotrophins alter the extracellular matrix, increase the density and distribution of nerve fibers, and induce the production of others proinflammatory cytokines.¹⁴ These changes result in further nerve ingrowth into the intervertebral disc, synthesis of pain-related peptides, and transmission enhancement of pain signals in the dorsal horn of the spinal cord.^{14,15} Pain is then transmitted through a rich nerve plexus that surrounds the outer surface of the degenerative annulus. The nerve plexus is made up of the meningeal branches of the sinuvertebral nerves that enter the spinal canal through the neural foramen and bifurcate into ascending and descending branches.

CLINICAL ASSESSMENT AND DIAGNOSIS

The typical patient with a symptomatic annular tear will present with axial back pain with or without leg pain radiation. The location and intensity of the pain will vary from patient to patient. The author has found that extension posture according to the technique demonstrated by McKenzie is useful in the diagnostic process. If the patient experiences centralization of pain with this maneuver, it is more likely that the annulus is intact. On the other hand, a patient who does not achieve centralization with the maneuver is more likely to have annular disruption requiring intervention.^{15,16}

For patients with leg pain, there is generally good correlation between the side of the annular tear on MRI and the side of radicular leg pain. In some cases, EMG can be useful to correlate the level of the nerve root irritation.^{17,18}

The straight leg raising test is generally normal in cases of symptomatic annular tear with back or leg pain as the root is adequately mobile in the foramen. Alternatively, the Gore sign may be useful in detecting and confirming inflammatory involvement of the nerve root in

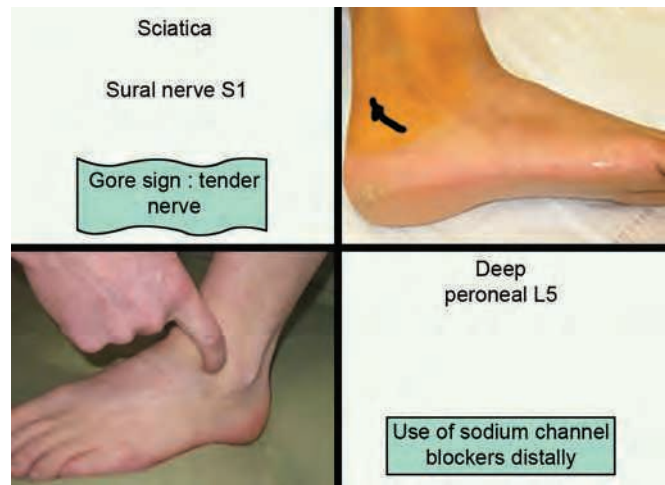

Fig. 77.3: The Gore sign can be elicited by palpating the deep peroneal or sural nerve over the lateral aspect of the ankle as demonstrated above.

sciatica associated with annular tears. To perform this test, the examiner palpates the inflamed symptomatic nerve rather than just depend on pain distribution and dermatomal understanding or enhanced MRI to diagnose the radicular involvement.¹⁹ Specifically, the Gore sign can be performed by palpating the lateral terminal branch of the deep peroneal nerve to assess L5 involvement and by palpating the sural nerve to assess S1 symptoms (Fig. 77.3).

Imaging

Plain radiographs are only able to identify the changes associated with the later stages of the degenerative cascade such as disc space narrowing, osteophyte formation, and segmental deformity. They are therefore not helpful for early stage interventions. MRI with T2-weighted imaging is, however, able to show dehydration, blurring of the annulus/nucleus junction, and bright signal within the annulus at the sight of a high intensity zone (HIZ). HIZ may be correlated with a positive response to provocative discography and may be a marker for discogenic pain. However, an HIZ can also be seen in some asymptomatic patients.

Annular tears are also evident on gadolinium enhanced T1 weighted imaging which can be used to demonstrate the vascularized granulation tissue within the margins of the annulus.^{20,21} In some cases, pooling of gadolinium may be observed around symptomatic annular tears, suggestive of neovascularization and inflammation due to a leakage of cytokines from the disc via the annular tear.²²

When assessing the MRI studies, it is important to ensure that the disc remains contained, if an annular repair procedure is to be planned. In particular, the posterior and posterolateral annulus should be carefully studied as this region has been shown to be the primary symptom generator.

Discography

Discography (Fig. 77.4) is a potentially useful tool when assessing a patient with severe axial back pain thought to be of annular origin. Discography can demonstrate the morphologic characteristics and integrity of the disc, as well as the location and size of the tear. With current techniques, discography is more accurate than MRI for the detection of annular pathology as a normal MRI does not exclude structural disruption of the annulus.²³⁻²⁵

Transforaminal Endoscopy

Transforaminal endoscopy provides a powerful tool to assess the annulus for pathologic involvement as the tissue integrity, presence of nuclear material, and inflammatory tissue in the region of the defect can be directly observed. Transforaminal endoscopy under local anesthesia has begun to replace other invasive studies, such as provocative discography in the practice of some experts in the field.

Fig. 77.4: Discography—lateral film of L5-S1 intervertebral disc demonstrating contrast leaking out into the epidural space through an annular tear.

Operative Planning

Anatomy of the Target Area

The disc height must be assessed preoperatively and should be sufficient to allow entry and free movement of the endoscope within the disc space. The posterior annulus can be conceptually represented by a rectangle bound by upper and lower endplates at the level of the disc, and the borders of the pedicle on both sides in a coronal or AP image. Normal interpedicular distance varies from 24 to 36 mm as one descends from the L1 to the S1 level.

With a unilateral transforaminal approach, the annulus from the entry site in Kambin's triangle to midline may be accessed. If the tear is more extensive than what can be addressed with a unilateral approach, bilateral biportal access must be considered.

Using transforaminal access, area of an annular tear can be debrided and then treated with thermal energy to create shrinkage and closure of the torn tissue. This type of annuloplasty can also be performed from inside the disc, avoiding the formation of epidural scar tissue within the spinal canal.

Transforaminal Surgery

The patient is positioned prone on a radiolucent table. Using the image intensifier, the bony landmarks are marked out on the skin. This includes the midline, disc space and medial borders of the pedicles. Using lateral fluoroscopy, the inclination angle of each disc space is also demarcated. The entry for access to a given disc is at the intersection of AP and lateral lines, approximately 10–12 cm lateral to the midline.

Access to L5/S1 level is generally through the same skin incision as the L4/L5 level. Due to the inclination of the disc and the presence of the iliac crest it is mandatory to go above the crest. After making a small 8 mm skin incision, a 25 cm long spinal needle is used to establish the trajectory to the disc space, after which local anesthesia is injected along this tract—including the sensitive area of the ipsilateral annulus. The angle of the needle is generally about 25–30° above the horizontal plane in a prone patient. The needle tip extends into the foramen and docks on the annulus at the level of the medial pedicle.

After establishing and anesthetizing the tract to the annulus, the dilator is inserted (at the same angle), followed by the endoscopic cannula which is docked bluntly against the margin of the disc. Using a 25° endoscope,

inspection of the annulus and foramen can be carried out. At this stage, it is common to observe the presence of disc fragments in annular defects and vascular granulation tissue along the margins of the annular tear. Using probes, the tissue can be assessed, and fragments of nucleus are mobilized and removed. All loose nuclear material within the annular defect is removed prior to treating the area with radiofrequency or laser energy to shrink the tissue and close the tear. Prior to withdrawal of the endoscope, the traversing and exiting nerve roots are inspected and mobilized as the endoscope is withdrawn to the annular surface.

CASE EXAMPLE

The sagittal MRI of a patient with chronic lumbar discogenic pain demonstrates a radial annular tear at the L5-S1 level. Due to the severity of symptoms, the patient was offered transforaminal endoscopic treatment. During surgery, the posterolateral annulus was examined. At the beginning of the procedure, the nucleus pulposus was injected with indigo carmine stain. During endoscopy, the blue color of the nucleus was seen along with red granulation tissue. The nucleus tissue was debrided revealing the annular tear and granulation tissue adjacent to the tear. The annular tear was then treated with electrothermal annuloplasty (Fig. 77.5).

Aftercare

The use of an orthosis postoperative is not routinely recommended. Basic activities of daily living can be

initiated as tolerated at the time of discharge. Activity restrictions can be lifted at 4–6 weeks following surgery at which point physical therapy that focuses on core strengthening and stability can be initiated. The typical course of healing may vary depending on the thickness of annular tear, but it generally occurs over 3–6 months.

Complications

Complications can include as nerve root injury, spinal cord injury, infection, epidural abscess, discitis, and scar tissue formation. The use of laser and RF probes near the nerve and dorsal root ganglion can result in dysesthesias, which are usually self-limiting and subside within 4–6 weeks. More severe dysesthesia can also be treated with foraminal epidural blocks or with oral gabapentin.

Outcome

The literature support for the treatment of annular tears is variable depending on the mode of treatment. Due to high association of annular tears with other lumbar pathology, the indications for treatment of many of the clinical trials includes chronic discogenic pain which in part is attributed to annular tears.

Primary closure of annular tears with suture has largely been limited to biomechanical and animal studies. Suture repair has been shown to restore the mechanical integrity of the annulus fibrosus.²⁶ Also, in a porcine model, suture repair demonstrated reduced inflammatory changes over time and slower progression of disc degeneration compared to no repair of annular defect.²⁷

Other alternative includes intradiscal electrothermal therapy (IDET) and intradiscal radiofrequency thermocoagulation (IRFT). The proposed mechanism for these types of annuloplasty is ablation of nociceptors and shrinkage of collagen fibers to stiffen the IVD. In a prospective case series comparing IDET and lumbar fusion surgery, the IDET group showed a statistically significant and clinically meaningful improvement in pain and functional outcomes at a minimum follow-up of one year.²⁸ Similarly in a case-control study, almost 90% had a statistically significant improvement in pain scores and all patients in the treatment group returned to work.²⁹ In contrast, in the control group, which underwent a physical rehabilitation program, only one patient had a significant improvement of pain and more than half of the 17 patients had worsening pain. Only 20% of the control group returned to work.

Fig. 77.5: Intradiscal electrothermal therapy (IDET)—intraoperative fluoroscopy of L5-S1 demonstrating catheter placement for IDET in the posterior annular wall.

One of the main concerns with annuloplasty is the potential for accelerated degeneration of the IVD. However, the efficacy of IDET is not uniformly supported. Freeman et al. conducted a randomized, double-blind controlled trial that IDET resulted in no improvement in functional outcomes at 6 months compared to baseline and the control group.³⁰ The current body of evidence for IRFT is limited with a small randomized double-blind study indicating that RF thermocoagulation is no more effective than placebo at eight weeks.³¹

The different types of annuloplasty are designed to approximate or reduce the size of the tear which prevents the nucleus pulposus from herniating and limits the ongoing inflammatory response. However, annuloplasty fails to restore damaged fibers and promote healing. Therefore, the search for biological treatments that enhance regeneration have been proposed. Biological treatments mainly consist of direct injection of regenerative substances, gene therapy, and tissue engineering. However, most biologic treatments have been restricted to in vitro and animal studies. Recently, platelet-rich plasma (PRP) has received more attention and has even been evaluated in human clinical trials demonstrating a potential role in intervertebral disc pathology. In one prospective, double-blind, randomized controlled trial, intradiscal autologous PRP resulted in better pain control, patient satisfaction, and functional outcomes.³² The readily available source of autologous multipotent stem cells from PRP and its supported use in other areas of orthopedics has made it an attractive option, but larger studies are still required.

SUMMARY

Annular tears occur as part of the degenerative process of the intervertebral discs. The most important tears from a clinical perspective are radial in nature, affecting the peripheral region of the annulus. Following the formation of an annular tear, the body may react with neovascularization and neurotization along the outer margins of the disc, eventually leading to symptoms of back pain or chemical irritation of nerve roots—potentially leading to sciatica. Annular tears can be detected by MRI or discography. Annular tears presenting as back pain can be treated by debridement followed by thermal or light ablation with shrinkage of the torn annulus. Annular defects which contain herniated nuclear material can be treated by transforaminal excision of the herniated material followed by approximation of the

annular defect by annuloplasty. The results of endoscopic treatment of selected annular defects appear promising, but are still limited small clinical trials and so large, prospective studies are needed to demonstrated the efficacy and long-term outcomes.

KEY POINTS

The annulus acts like a barrier between the nuclear tissue and the nerve fibers. Normal function of the spine requires integrity of the annulus. An annular tear may lead to back or leg pain. Surgical techniques to restore the annulus are being developed.

INTRODUCTION

Axial low back pain can be a disabling disease to a large percentage of the population. Over 90% of the United States population will suffer from back pain at some point in their lives, making nonoperative management of physical therapy, cognitive and behavioral therapy, and anti-inflammatory medications the mainstay of treatment. When back pain is unremitting and cannot be managed successfully with conservative care, surgical intervention can be discussed. Even then only a specific patient population may benefit. In order to provide cost-effective health care and consistent postoperative outcomes, spine surgeons must exercise selective indications.

DIAGNOSTIC WORKUP

Standard workup for low back pain includes obtaining anteroposterior (AP), lateral, and flexion–extension lumbar radiographs. These films should be scrutinized for findings suggestive of degenerative disc disease such as osteophyte formation, endplate sclerosis, facet arthrosis, and calcification of the intervertebral disc. Keeping the possibility for surgical intervention in mind, the lateral image can be studied for calcification of the great vessels in case an anterior approach is employed to reach the level of the intervertebral disc. Other degenerative pathologies such as degenerative or isthmic spondylolisthesis should be ruled out, in particular with flexion–extension films,

by screening for subtle translation of the vertebral bodies. Transitional anatomy and the level of the crest with respect to the involved intervertebral level should be noted for surgical planning.

Magnetic resonance imaging (MRI) is the standard of care to accurately assess the status of the intervertebral disc. More obvious findings include disc desiccation (commonly referred to as “dark nucleus” due to the loss of the hydration signal on the T2 sequence), high intensity zones in the posterior annulus (indicating a tear through which disc material can potentially herniate), Modic changes in the vertebral body endplates surrounding the disc, and collapse of disc height associated with bulging or herniation of the disc (Fig. 78.1). Modic changes are described by three stages¹: In stage 1, there is decreased T1 signal in the endplate and increased T2 signal thought to be associated with disruption and fissuring of the endplates and the presence of vascularized fibrous tissue ingrowth or edema. In stage 2, there is increased signal in the endplate on T1 and isointense signal in T2, associated with yellow marrow replacement or deposition of fat. Modic stage 3 changes are indicative of advanced degenerative changes such as endplate sclerosis, and the signal on both T1 and T2 is decreased within the endplate. In addition to disc changes on MRI, signs of facet degeneration or arthrosis may be present including facet hypertrophy (resulting in encroachment on the central canal and spinal stenosis) or loss of articular cartilage.

Fig. 78.1: Degenerative disc disease: Classic findings on this sagittal T2-weighted image include desiccated disc, loss of height, disc bulging, Modic changes in the vertebral endplates.

In the setting of back pain, it is simple to identify the potential source of pain in those patients whose MRI demonstrates a single level of involvement. On the other hand, when there is a spectrum of findings at multiple levels, the source is more difficult to elucidate. Since surgical morbidity and success rate of treatment follow opposing trends as the number of levels operated on increases,² it is important to attempt to identify which disc is the most likely pain generator. Boden et al. performed MRIs on 67 asymptomatic individuals and found that the approximately 33% of them had substantial abnormality.³ Of those older than the age of 60 years, 57% had an abnormality and this incidence significantly increased to almost 100% in those aged 80 years. Borenstein et al. performed a 7-year follow-up on these patients and demonstrated that findings of degenerative disc disease on MRI were not predictive of development of low back pain or duration of related symptoms.⁴ This would imply that despite findings of degenerative disc disease at multiple levels, all of those levels may not necessarily be responsible for a patient's symptoms.

Discography is a diagnostic tool that is believed to help ascertain whether a disc that has radiologic signs of degeneration is responsible for clinical symptoms. Under fluoroscopic guidance, a needle is inserted into the targeted disc. The opening pressure is then measured using a manometer. A specific volume of fluid is then injected into the disc while making continuous pressure recordings with an upper limit of pressure measured set, at which the test

will be aborted. As the disc is injected, the patient is asked to determine whether they experience pain secondary to this procedure similar in character to their usual low back pain. If this is the case, the discogram is determined to be concordant, and the pressure at which the symptoms are generated is recorded. If the pressure limit is reached without recreation of symptoms, the discogram is determined to be nonconcordant.⁵ The use of discography, however, is controversial. Carragee et al. performed a prospective match-controlled study of disc degeneration over 10 years with and without baseline discography.⁶ Those discs that had been exposed to puncture and injection had progression of disc degeneration at a 35% incidence in the discography group compared with 14% in the control group. New disc herniations were disproportionately found on the side of the annular puncture, and there was a significant difference found in measurements of disc height and disc signal intensity in the two groups. This alarmed the spine community to the potential hazards of diagnostic testing with discography as it is often the case that a control disc with minimal signs of degeneration is injected in addition to the degenerative disc to add validity to the test results. Carragee et al. as well as multiple other groups have studied the false-positive rate of discography and have found results as high as 25%, with accuracy of the test diminishing in the presence of psychosocial history or chronic pain syndromes.⁷⁻¹⁰ Other critics of the tool also emphasize that the result is based on a subjective patient response and therefore can be subject to significant confounding bias. Thus, the surgeon must be wary in use of discography as an adjunct to surgical planning in those with degenerative disc disease and chronic low back pain.

■ NONOPERATIVE MANAGEMENT

There is a wide breadth of nonoperative modalities that are available to patients with disabling chronic low back pain. Prior to arriving at a surgical discussion, all reasonable options should be exhausted. There is a significant body of literature that exists on various means to approach back pain. Mainstays of treatment include activity modification, use of nonsteroidal anti-inflammatory medications with special attention to any conflicting comorbidities, and physical therapy that emphasizes core strengthening. More recently, studies have included a focus on cognitive behavior therapy as part of the physical therapy. Brox et al. performed a randomized study on lumbar fusion versus cognitive intervention and exercise, and found equal improvements in patients with chronic low back pain to

those treated with lumbar fusion.¹¹ There are multiple alternative therapies that are available to patients as well including treatment by a chiropractor or acupuncturist. Though the literature does not yet validate the use of these modalities, patients often report symptomatic relief.

SURGICAL TREATMENT

Candidates for surgical intervention include patients with chronic disabling low back pain that have trialed various nonoperative modalities and have signs of degenerative disc disease on imaging studies. Careful selection of patients including assessment of psychosocial factors, medical comorbidities, and functional reserve is critical to achieving optimal outcomes.

Prior to the advent of motion sparing technologies, the most common surgical treatment for chronic axial back pain in the appropriately selected patient was lumbar fusion. Prior to the use of instrumentation, this was accomplished with a posterolateral fusion between the transverse processes. At present, there are multiple methods to accomplish a lumbar fusion and these may or may not include pedicle instrumentation as well as an interbody fusion.

The goal of any fusion, regardless of technique, is to eliminate motion in the lumbar motion segment. Previously it was thought that motion at the lumbar spinal unit was responsible for the pain. In degenerative disc disease, the disc is thought to be the pain generator. Therefore, the goal of the fusion in this setting is to eliminate motion while also removing the disc. The approach to the disc is the main differentiating factor between techniques that have been developed to obtain an interbody fusion.

Posterolateral Fusion

Before the implementation of instrumentation, fusions were obtained in the posterolateral bed between the transverse processes. A midline lumbar skin incision was made and used to expose the midline elements, the posterior facet capsules and joints, and the transverse processes of the levels to be fused. Care is taken to preserve the facet capsule of the cephalad level, and decortication of the index facet, pars, and transverse processes of the levels to be fused is performed. The goal is to stimulate bony bleeding and thus deliver osteogenic cells to the fusion bed. Various bone substitutes that are both osteoinductive and osteoconductive can then be added to the fusion bed and allow for a bony mass to form in this area to create a stabilizing effect between the two functional spine units. The

main concern about treating degenerative disc disease with a posterolateral fusion alone is the potential for pseudoarthrosis and thus continued motion at this level resulting in persistence of pain symptoms. However, for a single level noninstrumented fusion in the setting of degenerative disc disease, McCulloch has reported a 91% fusion rate with successful clinical outcomes.¹²

Instrumentation in the form of pedicle screw-plate systems and pedicle screw-rod systems afforded semirigid and rigid constructs, respectively. Theoretically, these constructs maintain temporary fixation while bone is generated in the posterolateral fusion bed. Whether or not these systems improved fusion rates and, moreover, clinical outcomes is debated throughout the literature. Though this topic has been the focus of multiple studies, the various diagnoses included in those who underwent fusion by these systems makes it difficult to discern whether instrumentation truly improves fusion rate and clinical outcomes. France et al. demonstrated a fusion rate of 76% versus 64% in instrumented versus uninstrumented fusions with the use of variable screw placement (VSP), a semirigid system.¹³ Their population included patients with degenerative spondylolisthesis as well as degenerative disc disease. Importantly, they showed no statistically significant difference in clinical outcome scores. On the other hand, Lorenz et al. compared a single-level fusion with VSP versus uninstrumented fusions and found statistically significant differences in fusion rates, pain improvement scores, and return to work between the two groups.¹⁴ Their patient population included only those patients with chronic disabling discogenic pain for >6 months. Zdeblick et al. also demonstrated >90% fusion rates and outcome success with rigidly instrumented fusions when compared with semirigid fusion and posterolateral fusion alone.¹⁵ Thomsen et al. conducted a randomized prospective study in which they were unable to demonstrate sufficient benefit from instrumentation in either fusion rate or clinical outcome over those who did not receive instrumentation.¹⁶ Both groups had a high rate of fusion and successful outcomes. Given the significant risks associated with instrumentation including potential nerve root damage from aberrant screw trajectories, they warned against routine use of pedicle instrumentation in adjunct with posterolateral fusions.

Interbody Fusion

As mentioned above, an additional surface across which a fusion can be obtained is the vertebral endplate. This is

termed an interbody fusion. There are multiple methods to approach the intervertebral space with the common goal of removing the pathologic disc and obtaining a bony bridge between the vertebral bodies. As opposed to the tension forces that are present between the transverse processes posteriorly in the erect position, compressive forces are present anteriorly between the vertebral bodies. This, in combination with the large surface area of the endplate, leads to a higher chance of successful fusion. Studies have focused on whether clinical outcomes are improved with interbody fusion as, theoretically, removal of the disc itself directly addresses the pain generator in degenerative disc disease. In addition, biomechanical studies such as those by Lee and Langrana have shown that while posterolateral fusions can increase axial stiffness by 40%, anterior interbody fusions can increase this same parameter by as much as 80%.¹⁷ The greater the stabilization at a given motion segment, the greater the theoretical pain relief. Barrick et al. found that patients experienced pain relief with anterior lumbar interbody fusion (ALIF) after prior posterolateral fusion had been performed.¹⁸ Weatherley et al. had similar results of pain relief in five patients who despite showing a solid posterolateral fusion had significant pain and subsequent pain relief with performance of an ALIF.¹⁹ More recently, however, Høy et al. have documented that patients with degenerative disorders did not significantly do better with a transforaminal lumbar interbody fusion (TLIF) when compared with posterolateral instrumented fusion.²⁰ Whether this is attributable to the type of interbody cage, placement of the cage, lordosis gained, or other clinical parameters, is a subject of debate. Much like the controversy that exists with instrumentation, further studies would be needed to delineate whether an interbody fusion is universally superior to a posterolateral instrumented fusion.

Anterior Lumbar Interbody Fusion

The first described interbody fusion was performed via an anterior approach in the 1930s. Burns described this operation as a treatment option for a diagnosis of spondylolisthesis.²¹ In the 1970s, Crock described a disorder termed internal disc disruption occurring after intervertebral disc lesions (i.e. herniations) and his treatment by ALIF.²² Today, there are a multitude of methods by which ALIF can be accomplished with the use of bone grafting, various cage devices, and advanced osteobiologics. The anterior approach is performed either by a longitudinal

incision, especially in the case of multilevel interbody fusion for access to multiple levels and adequate exposure, or by a low-lying transverse abdominal incision. In most cases, the surgeon gaining access will dissect lateral to the rectus abdominis and then proceed either in a transperitoneal or retroperitoneal fashion to reach the aorta and inferior vena cava overlying the anterior disc spaces. Careful dissection must be performed of the vessels away from the anterior longitudinal ligament, and specialized retractors are used to maintain their position and access the disc space to perform the interbody fusion.

Retrograde ejaculation (RE) is a potential complication associated with the anterior approach that can occur as the parasympathetic plexus is dissected through or swept away from the field in order to gain access to the disc space. Sasso et al. have reported a higher incidence of RE in a single-level anterior interbody fusion with a transperitoneal approach (13.3%) as opposed to the retroperitoneal approach (1.7%).²³ At 2-year follow-up in their cohort of patients, 10% and 0.86% of patients had permanent RE in these respective groups. In the past decade, much research has focused on the increased incidence of RE with the use of recombinant human BMP-2 (rhBMP-2) as an osteogenic supplement to the ALIF. Though this concern was identified in initial Food and Drug Administration (FDA) trials with rhBMP-2, the true incidence of RE remains debated. Carragee et al. performed a retrospective analysis in which they identified RE in 7.2% of two-level ALIF patients in whom rhBMP-2 was used versus 0.6% of those patients in whom the synthetic recombinant protein was not used.²⁴ When assessing single-level ALIFs, there was a 6.7% rate of RE in those who received rhBMP-2 versus 0% in those patients who did not. Burkus et al. pooled the data from five different prospective randomized multicenter FDA Investigational Device Exemption (IDE) trials.²⁵ With their combined population, they found that 3.4% of those in whom rhBMP-2 was used developed RE versus 1.7% in those in whom it was not used. This difference was not statistically significant, however. They also confirmed a much higher incidence of RE with a transperitoneal approach of 8.6% versus 1.6% with the retroperitoneal approach. Recently, Tepper et al. have highlighted that the mechanism by which RE is reported may play a critical role in determining the true incidence of the complication.²⁶ This group showed that the typical questionnaire used to report RE may overestimate the incidence. In fact, when using quantitative semen and urine analysis, the incidence of RE found in comparative cohorts with and without the use of

rhBMP-2 for ALIF was almost identical at approximately 10%. Regardless, the preoperative discussion held with a patient regarding potential for sterility from the anterior approach is an important part of the decision to pursue surgical intervention.

Once the targeted disc space has been exposed via an anterior approach, an annulotomy is performed and the entirety of the disc is removed. The cartilage from the endplates is removed to reach bleeding subchondral bone. The disc height and space are then restored with some combination of autograft, allograft, osteobiologics, and/or an intervertebral cage device. In the earlier attempts at anterior interbody fusion, various forms of autograft were used. The first described was an autologous tibial peg. More commonly, prior to the advent of cages if autograft was used it was in the form of a tricortical iliac crest autograft. Over time, the interbody has evolved to a cage design packed with some form of bone or osteobiologic, as the cage is designed to temporarily stabilize the interspace as the bone bridge is formed between the endplates. Dennis et al. showed that in fact there can be loss of disc height over time as fusion is achieved and therefore it is important for the cage to be able to withstand physiologic mechanical loads during the incorporation process.²⁷

The initial attempts at interbody fusion from an anterior approach were by implantation of material into the disc space to allow for a fusion without the addition of supplemental instrumentation. This is termed a “stand-alone ALIF.” The quoted rates of fusion for treatment of symptomatic degenerative disc disease with an ALIF are variable. Chow reported on 97 patients treated with autogenous corticocancellous bone graft and had a fusion rate of approximately 63%.²⁸ Loguidice et al. treated 85 patients with either autograft (tricortical or dowel) or allograft and had a cumulative fusion rate of 75%.²⁹ Blumenthal documented a similar rate of 73%.³⁰ Newman and Grinstead had a much higher success rate at 89%, demonstrating fusion with lack of motion of flexion-extension radiographs.³¹ With the introduction of threaded cylindrical cages, the rate of fusion for ALIF was consistently elevated above 90%. Kuslich and Bagby published a single-level fusion rate of 98% in an FDA effectiveness trial while two levels had a fusion rate of 80% with the use of BAK (Bagby and Kuslich; Spine-Tech, Minne Polis, MN) cages composed of titanium.³² Sasso et al. found a 60% fusion rate in a control arm treated with a femoral ring allograft packed with autograft bone, while their experimental arm treated with a cylindrical titanium

cage packed with autograft had a 97% radiographic fusion rate at 2 years follow-up.³³ Thus, the quoted rate of anterior fusion varies from approximately 60% to 90% in the literature.

Advantages of the anterior approach include the ability to restore disc height, lordosis, and foraminal patency. In addition, the need for posterior spinal musculature dissection and healing is obviated. Complications associated with pedicle screw placement are also avoided. The majority of complications and thus disadvantages associated with the anterior approach are a result of the approach itself. As a result of manipulation of the bowel contents to access the spine, patients may suffer from ileus or actual injury to the abdominal contents themselves. Vascular complications can occur, more often during the annulotomy, discectomy, and placement of the cage than during the exposure itself. The range of potential vascular injuries is from minor to life threatening given the involvement of the great vessels. Retrograde ejaculation was discussed above. In addition, as with any fusion procedure, the risks of subsidence of the graft, pseudoarthrosis, graft extrusion, and implant failure do exist. Subsidence can be reduced with appropriate sizing of the graft to the body, maximum contact surface area between graft and vertebral body, and complete preparation of endplate surfaces. Over time, ALIF cages have also evolved to include supplemental screw fixation into the adjacent vertebral bodies such as Synfix (DePuy Synthes: West Chester, PA). Other options for improved stabilization, reduction of subsidence, and prevention of graft extrusion, include anterior plating and the standalone interbody cages.³⁴⁻³⁶ Tzermiadianos et al. have shown in a biomechanical model that the use of a ATB plate (DePuy Synthes) in addition to a cage can significantly decrease the range of motion in flexion and extension comparable to the use of posterior pedicle screw augmentation.³⁷ Nichols et al. also confirmed the equivalent stability of an anterior plate to posterior instrumentation.³⁸ Gerber et al. have demonstrated an increase in axial stiffness equivalent to that of posterior supplementation.³⁴

Circumferential Fusion

Another means to treat lumbar degenerative disc disease is to perform a circumferential fusion. By utilizing both the anterior vertebral body surfaces and the posterior fusion bed, the rate of fusion is higher. This is at the cost of a larger procedure with the associated morbidities. A circumferential fusion can be obtained in multiple ways: ALIF plus posterolateral fusion, ALIF plus open posterior

Figs. 78.2A and B: Anteroposterior and lateral X-ray of circumferential fusion: Anterior lumbar interbody fusion with posterior instrumentation.

instrumented fusion, ALIF plus percutaneous pedicle screws, posterior-based instrumented fusion and lumbar interbody fusion (PLIF or TLIF)—the entire procedure can be performed through the posterior approach, or lateral interbody fusion with percutaneous pedicle screws (Figs. 78.2A and B). Given the potential increased operating time, hospital stay, transfusion need, and overall complication rate compared with a stand-alone fusion, patients who undergo a circumferential fusion must be carefully selected. This approach to fusion is advantageous in the setting of revision surgery, those at high risk for subsidence, and in diabetics and smokers.

There is ample literature to support a higher fusion rate in those patients receiving circumferential fusion. The improvement in clinical outcome, however, has been questioned. Kozak et al. gave validity to the technique of a circumferential fusion by demonstrating a >90% fusion rate in single- and double-level fusions performed for discogram-positive patients with low back pain.³⁹ In multilevel patients, the fusion rate fell to 78% but overall they still found acceptable clinical results in 80% of those with primary low back pain. Gertzbein et al. performed circumferential fusions with semirigid instrumentation on patients who had failed prior surgery, including those with pseudoarthrosis, as well as patients who were heavy smokers.⁴⁰ They showed a 97% fusion rate, significant reduction in pain scores, and that 77% of patients returned to a satisfactory level of activity. Hinkley and Jaremko studied the effects of circumferential fusion in a workers compensation population and found that 91% of the 81 patients treated had reduced pain and disability, thus

demonstrating a positive response to treatment.⁴¹ Moore et al. performed combined anterior and posterior fusions in those with chronic back pain and degenerative disc disease using two tricortical iliac crest allografts anteriorly and a posterolateral fusion with Cotrel-Dubousset instrumentation.⁴² They documented a 95% solid arthrodesis rate, with 86% clinical improvement as patients showed a decrease in pain on the visual analog scale (VAS) and improvement in functional questionnaires.

Randomized controlled trials (RCTs) have also been performed to compare the fusion rates and outcomes of posterolateral fusion with circumferential fusion. Fritzell et al. performed a prospective multicenter RCT comparing patients with chronic low back pain treated by three different modalities: (1) posterolateral fusion, (2) posterolateral fusion with VSP, and (3) posterolateral fusion with VSP and an interbody fusion (either an ALIF or PLIF).⁴³ At 2-year follow-up, they were able to again confirm the higher rate of fusion with circumferential procedures, as the respective rates of fusion were 72%, 87%, and 91%. Interestingly, they were not able to show a significant difference in clinical outcomes between groups. On the other hand, Videbaek et al.⁴⁴ documented long-term 5- to 9-year follow-up on a RCT by Christensen et al.⁴⁵ between posterolateral fusion with Cotrel-Dubousset instrumentation versus circumferential fusion with ALIF and posterolateral instrumented fusion. The initial tendency toward better functional outcome shown by Christensen at 2-year follow-up was significantly better at long-term follow-up. This was the case in terms of general health, daily activity, and Oswestry Disability Index. More recently, Høy et al. compared

circumferential fusion with a TLIF and posterolateral fusion with Texas Scottish Rite Hospital instrumentation and did not find a significant difference in clinical outcome.²⁰ Thus, with major RCTs in the literature providing conflicting evidence, clinical outcome of circumferential fusion is debatable. However, it can be asserted that circumferential fusion does have an increased fusion rate and a decreased reoperation rate despite the potential associated morbidities of a more extensive surgical procedure.

As mentioned above, there are methods by which to obtain a circumferential fusion without performing an ALIF. These are all posterior-based procedures and include either the PLIF or TLIF. Though the ability to perform these procedures is sometimes limited by patient anatomy (i.e. narrow pelvis), excessive adherence in the setting of a revision, or difficulty of exposure in the setting of a muscular or coagulopathic patient can be performed through a single posterior incision—thereby avoiding the additional morbidity of an anterior approach.

Posterior Lumbar Interbody Fusion

The PLIF is performed through a midline lumbar incision. A laminectomy is performed at the desired level of interbody fusion. A bilateral partial facetectomy is also performed allowing for retraction of the dura to access the intervertebral disc space and perform annulotomy. Two cages are placed within the interbody space following annulotomy, disc removal, and endplate preparation; one cage from either side. In the case of TLIF, the same incision is used, but the laminectomy is not necessary. In an open bilateral exposure, pedicle screws and rod construct may be placed on either side, preferably on the side into which the cage will be inserted. Distraction is then applied across the screws to allow access to the disc space. Headless screws can be temporarily used to limit interference with cage insertion. The inferior facet is completely removed, thereby necessitating less retraction of the dura than is present in the case of a PLIF to access the disc space. Again the same steps are taken including annulotomy, discectomy, and endplate preparation followed by placement of a single cage in the intervertebral space. One technique involves aiming the cage to the diagonal anterolateral corner of the disc space and then using a specialized inserter to flatten the cage out. The PLIF technique has fallen out of favor given the increased potential for dural tears, conus injury through excessive retraction, and enhanced epidural scarring from dural manipulation. The TLIF helps

avoid some of these risks, but, like the PLIF, still places the nerve root at risk for injury, and requires instrumentation given the complete takedown of the facet. In addition, if it is necessary, the TLIF procedure allows for thorough decompression of the nerve root. The fusion rate for TLIF and ALIF are similar, however, Hsieh et al. found that ALIF is superior to TLIF in its ability to restore foraminal height, local disc angle, and lumbar lordosis which may have implications in terms of overall sagittal balance.⁴⁶

Minimally Invasive Surgery

While the traditional means of obtaining a fusion, whether anterior, posterior, or circumferentially, has been in an open fashion, there are also several minimally invasive options. Those who favor minimally invasive approaches cite limited muscle dissection and crush injury (especially posteriorly), minimal blood loss, projected shorter operating times (once past the learning curve), and reduced length of inpatient stay as advantages. In particular, when decompression is not needed, the following techniques can be viable alternatives.

The first type of minimally invasive spine surgery performed was in the form of percutaneous pedicle screws. These were described by Magerl in 1982,⁴⁷ as a component of an external fixator used in traumatic situations. Magerl also documented the use of a translaminar facet screw in an open fashion, which has since been rivaled by a minimally invasive counterpart. In the 1990s, the advent of several endoscopic procedures in both general and urologic surgery spurred the generation of minimally invasive anterior and retroperitoneal approaches to the lumbar spine in the setting of fusion for low back pain.

Minimally Invasive Surgery (MIS) ALIF

There are three common minimally invasive approaches to the anterior lumbar spine including the mini-open retroperitoneal, laparoscopic transperitoneal, and endoscopic retroperitoneal. To perform a mini-open retroperitoneal approach, a 3–4 cm transverse incision is made in line with the trajectory needed to get to the disc level marked by fluoroscopy. This incision is made slightly to the left of the midline allowing for dissection to the anterior rectus sheath and then lateral to the rectus abdominis. This plane is then followed to the peritoneum, which is then separated from the lateral wall to access the retroperitoneum. Self-retaining retractors are then used to hold the

peritoneal contents out of the way, and vessels are then carefully dissected free from the anterior spine. The endoscopic retroperitoneal approach is performed in the lateral decubitus position via a 2–3 cm transverse incision centered over a line drawn from the eleventh rib to the anterior superior iliac spine. Blunt dissection is used to the retroperitoneal fat layer, and a dissection balloon is then inserted and inflated to create a retroperitoneal space. The balloon is then removed and self-retaining retractors or carbon dioxide insufflation is used to maintain this space. Ports can be made to insert working instruments, endoscope, and retractor blades. The psoas is elevated, and the anterior spine is exposed. Finally, in the case of a laparoscopic transperitoneal approach, multiple 1–2 cm incisions are made through which a scope, dissecting instruments, and retractors (as needed) are inserted. These instruments are used to dissect through the posterior peritoneum over the desired intervertebral space, with blunt dissection used for the retroperitoneal fat to limit parasympathetic plexus injury. This approach is limited at L4–L5 given the bifurcation of the great vessels.

The major disadvantage cited for laparoscopic transperitoneal approaches in comparison to retroperitoneal approaches is the risk of RE secondary to injury to the parasympathetic plexus (superior hypogastric plexus). This was mentioned above in the section on anterior approaches. In an initial series of patients who received laparoscopic ALIF, Zdeblick noted a 6% incidence of RE.⁴⁸ In a separate prospective study comparing laparoscopic and mini-open ALIF, Zdeblick and David found no differences in operating time blood loss, or length of stay for a single level, as well as higher complications at L4–L5.⁴⁹ Escobar et al. in a review of various minimally invasive techniques including those undergoing endoscopic retroperitoneal and laparoscopic transperitoneal approaches documented a greater need to convert to open intervention secondary to complications.⁵⁰ The limited exposure gained by laparoscopic techniques as well as the need to ligate the iliolumbar vein in the approach to L4–L5, in particular, can be problematic. There is a significant learning curve associated with laparoscopic transperitoneal approaches and even endoscopic retroperitoneal approaches, while the mini-open retroperitoneal approach is more easily developed for both access and spine surgeons alike.⁵¹

MIS PLIF/TLIF

With respect to posterior minimally invasive techniques, the risk profile of the PLIF versus the TLIF parallels the

open approach secondary to the need for medial retraction of nerve root, as well as takedown of midline structures. Both minimally invasive approaches involve the use of a paramedian incision that is centered over the disc space and the use of METrx (Medtronic: Minneapolis, MN) tubular dilators to reach the target point. In an MIS PLIF, bilateral incisions are made 2.5 cm lateral to the midline, while the MIS TLIF uses a unilateral 4.5–5 cm lateral to the midline incision. The MIS PLIF requires a hemilaminectomy and medical facetectomy with resection of the ligamentum flavum to be able to retract the nerve root medially. Once the disc space is accessed and interbody device is placed, tubular retractors are removed for placement of percutaneous pedicle screws to stabilize the disc segment. In the unilateral MIS TLIF, a total facetectomy is performed using a bayoneted osteotome, and the lateral most aspect of the ligamentum flavum can be taken down to visualize the exiting nerve root if desired. Distraction across the disc space can be performed by larger tubular dilator insertion. A smaller contralateral incision can be used in the case of an MIS TLIF to create distraction between the spinous processes with a laminar spreader or to place a contralateral percutaneous screw and rod construct through which distraction can be applied. An additional modification to the unilateral MIS TLIF technique has been to place a contralateral facet screw as a supplement to the unilateral pedicle screws, thereby avoiding further dissection, potential muscle injury, increased operating time, and abutment of a pedicle screw against the intact facet above (thought to play a role in the creation of adjacent segment disease).⁵² This can be done through a standard incision or in a percutaneous fashion as well. Both Slucky et al. and Schleicher et al. showed that a unilateral TLIF with pedicle instrumentation supplemented with contralateral facet screws had no significant difference in range of motion biomechanically when compared with a TLIF with bilateral pedicle screws.^{53,54} On the other hand, a unilateral TLIF without contralateral supplementation did have significantly less stiffness. Sethi et al. have documented the cost-effectiveness of such a construct involving facet screws.⁵⁵

Multiple studies have confirmed that the minimally invasive TLIF technique, when compared with the traditional open TLIF has resulted in less initial postoperative back pain, reduced intraoperative blood loss and need for transfusion, quicker time to ambulation, reduced hospital length of stay, reduced soft tissue injury (as measured by creatine kinase levels), and quicker functional

recovery.⁵⁶⁻⁵⁹ Seng et al. recently published a retrospective analysis of prospectively conducted study with mid-term follow-up of 40 matched cases of open TLIF versus MIS TLIF.⁵⁹ At 5 years, they found no significant difference in several validated outcome scores between the two groups and both groups had a fusion rate of 97%. With the additional benefits listed above, the MIS TLIF is a safe and effective option to consider.

XLIF/DLIF

An additional minimally invasive alternative to an open ALIF for an interbody fusion is an extreme lateral interbody fusion (XLIF), also known as a direct lateral interbody fusion (DLIF). This is an attractive option for interbody fusion with minimal takedown of native spine anatomy with the exception of the intervertebral disc. The patient is usually approached from the left side and therefore placed in the right lateral decubitus position. The operating table used allows for bending in the coronal plane, thus jacking open the left lateral aspect of the intervertebral space. Using AP fluoroscopy to identify the level and ensuring that the superior aspect of the iliac crest is not in the way (usually the case at L4-5), blunt dissection is carried down to the retroperitoneum to find the psoas muscle. The combination of dilators and electromyographic (EMG) monitoring is then used to dissect through the psoas while avoiding the lumbar nerve root plexus within the muscle itself to the lateral aspect of the intervertebral disc. The purported advantages of this minimally disruptive

approach are the ability to remove a large amount of disc material, placement of a large stable interbody implant, and retention of the anterior longitudinal ligament which is sacrificed in an ALIF (Figs. 78.3A and B). Biomechanical studies have been conducted to compare stand-alone lateral interbody fusions with or without instrumentation with ALIF constructs. Cappuccino et al. found that the lateral interbody cage had the largest stand-alone device reduction in range of motion compared with an ALIF and TLIF.⁶⁰ The addition of bilateral pedicle screws to create a circumferential fusion had the greatest stability. Others have recommended a lateral interbody fusion with unilateral pedicle instrumentation; however, this has an intermediate reduction in range of motion.

The most common concern expressed by spine surgeons with respect to the XLIF procedure is either vascular or neurologic complications, with specific focus on the lumbar plexus. Benglis et al. reported on the anatomy of the lumbar plexus after performing dissections on three cadavers.⁶¹ They found that the lumbosacral plexus was lying within the substance of the psoas muscle between the junction of the transverse process and the body and exited along the medial edge of the psoas distally. It migrated from dorsal at L1-L2 posterior endplate to ventral as it traverses down to L4-L5. It appeared, on an average of the dissections, to remain within the posterior one third of the disc space, and therefore dilators used during the approach should be “wanded” anteriorly. This should be corroborated by EMG monitoring as well as fluoroscopy. The genitofemoral nerve was found to be most at risk.

Figs. 78.3A and B: Extreme lateral interbody fusion: Performed via a minimally invasive approach, this extreme lateral interbody fusion was supplemented with unilateral pedicle screws.

While this study gave comfort to the idea of staying within the anterior two thirds, a more recent anatomic mapping study by Banagan states that there is no absolute zone of safety in this approach.⁶² With 16 cadaveric dissections, perforating branches of lumbar nerve roots were identified in anterior, middle, and posterior third of the psoas muscle placing both the roots and the genitofemoral nerve at risk. The lumbar plexus was also found to be placed under tension with sequential dilator placement. Again this highlights the necessity of supplemental EMG monitoring if this approach is to be taken. Regev et al. also examined the safe corridor within which discectomy and insertion of a cage can be performed from the lateral approach.⁶³ They again confirmed the narrowing of this safe corridor as one proceeds from L1-L2 down to L4-L5 and highlighted that preoperative MRI should be scrutinized for the location of important neurovascular structures.

Clinically, there is a limited amount of data in terms of outcome studies on XLIFs with respect to complications as the technique is relatively new. Knight et al. reported no vascular complications from the approach, and 2 out of 58 patients (3.4%) developed permanent motor deficits due to L4 nerve root injury.⁶⁴ In a more recent larger prospective analysis of 600 cases, Rodgers reported no vascular complications and 4 out of 600 patients developed a transient motor weakness which resolved within 3 months.⁶⁵ Postoperatively the L4 nerve root injury is most often manifested as quadriceps weakness and/or thigh or hip pain. Rodgers suggested premedicating with 10 mg of

dexamethasone IV preoperatively significantly reduced the transient motor deficit finding.⁶⁵ The incidence of complications with lateral interbody approaches compared with those reported for ALIF and TLIF are similar, and in some instances such as reported by Ozgur, they are close to nonexistent.⁶⁶

AxialLIF

A final minimally invasive means to obtain a lumbar fusion, in particular for L5-S1, is the percutaneous axial lumbar interbody fusion, also called AxialLIF. As initially described, a small incision is made above the coccyx, and a guide is maneuvered through the presacral or paracoccygeal space to the inferior aspect of the S1 body. This then allows for eventual removal of the central aspect of the disc and placement of a variable pitch axial screw through the vertebral body of S1 into L5 (Figs. 78.4A and B). The variable pitch is designed to create distraction as it is inserted. The cited advantages include the retention of the ALL, PLL, and annulus fibrosus while restoring disc height/lordosis through the distraction. Its usage has been expanded to attempts at two-level fusions, from L4-S1. Tobler et al. performed a retrospective case series review of 164 patients treated with AxialLIF for back pain thought to be secondary to degenerative disc disease, and at 2 years follow-up, 63% had an improvement in overall pain score, while 54% had an improvement in their ODI.⁶⁷ Radiographic fusion rate was 94%. A more recent study by Hofstetter et al. performed a retrospective analysis

Figs. 78.4A and B: AxialLIF: A large specialized screw with variable pitch was inserted through the presacral space to serve as the interbody fusion for two levels: L4-L5, and L5-S1. Supplemented with posterior instrumentation.

of 38 patients who underwent either single or two-level AxiaLIFs.⁶⁸ Overall, surgical outcomes demonstrated only modest symptomatic improvement, and fusion rates were 81% for single level, 33% for L5-S1 in a two level and 0% for L4-L5 in a two level. They asserted that the AxiaLIF provides inadequate long-term anterior column support, and there is thus significant risk for subsidence and loss of segmental lordosis. Other serious complications have been reported in the literature including rectal perforation requiring long-term intravenous antibiotic treatment with the creation of diverting colostomy as well as occasional retrieval of the device by sigmoidoscopy.⁶⁹ Further study of this technique and device is needed to deem it safe and effective for both one- and two-level interbody fusion.

Osteobiologics

Regardless of the type of fusion targeted, osteobiologics are a necessary component in obtaining a solid arthrodesis. Historically, fusion beds were filled with autograft, allograft, or a combination of the two. However, the morbidity associated with iliac crest bone harvest and the goal of improving fusion rates have spurred the advancement of osteobiologics used in spine surgery.

Osteobiologics contain one or more of the following properties: osteogenic, osteoconductive, or osteoinductive. That is, they either contain osteoprogenitor cells, serve as a scaffold on which bone cell reproduction can occur, or chemically signal surrounding cells to begin production of local bone and bone remodeling. In addition to the use of local autograft (morselized laminectomy bone) and allograft, several graft extenders with these properties are now available. They fall into the classes of bone morphogenetic proteins (BMPs), mesenchymal cells, and demineralized bone matrix.

In 1965, Marshall Urist documented the biological basis of bone morphogenesis by implanting dead bone matrix (decalcified) in the muscle pouches of rabbits.⁷⁰ He noted the presence of inductor cells and induced cells of the host bed, in which both cell lines were of the histiocyte lineage. In his later work, he used the term “bone morphogenetic proteins” to describe those molecules that were responsible for altering cell metabolic cycles in the induced cells to produce bone.⁷¹ Originally, seven BMPs were discovered, six of which belonged to the transforming growth factor superfamily. Today, there are approximately 20 BMPs known to exist. Bone morphogenetic protein-2 and BMP-7 have been manufactured in recombinant

formats and are FDA approved for clinical application. Bone morphogenetic protein-2 has most commonly been used in spinal surgery.

Initial studies on rhBMP2 indicated improved fusion rates with the reduction in donor site morbidity associated with iliac crest bone harvest. Boden et al. performed a human clinical pilot trial with 14 patients who received lumbar interbody fusion with threaded tapered cylindrical cages and rhBMP-2 or iliac crest autograft.⁷² They found that fusion was more reliably occurring in those treated with rhBMP-2 within the cage and reported no adverse events. Shortly after, Burkus et al. performed a multicenter, prospective, randomized, nonblinded study of 279 patients with degenerative disc disease between two groups that underwent anterior interbody fusion with two tapered threaded fusion cages using either rhBMP-2 applied to an absorbable collagen sponge or autogenous iliac crest bone graft, and found a fusion rate of 94.5% in the investigational group compared with the 88.7% in the control group.⁷³ Both groups had similar outcomes, while at 2 years, 32% in the control group reported donor site discomfort. Labeled on the market as Infuse (Medtronic), rhBMP-2 is applied to a bovine absorbable collagen scaffold. Multiple studies followed documenting the benefits of use of rhBMP-2 on cost-effectiveness, operating room time, blood loss, donor site morbidity, equivalence or superiority to fusion rates with iliac crest autograft, and equivalent validated outcome scores.⁷⁴⁻⁷⁶ Additional purported benefits also existed in challenging situations, such as retained fusion rates in smokers or patients aged >60 years. Glassman and colleagues demonstrated fusion rates for smokers receiving rhBMP-2 at 95% compared with smokers receiving iliac crest bone graft at 76%.⁷⁷ Carreon et al. also showed a reduction in complication rate and revision rate with patients over 60 years of age in a cost-utility analysis.⁷⁸

With increased use of rhBMP-2 in spinal fusion techniques, multiple studies have also documented the various complications that can be encountered.⁷⁹ They span a range including postoperative radiculitis⁸⁰ in both single-level open and minimally invasive TLIFs, postoperative seroma formation requiring evacuation both in cervical and lumbar applications,^{81,82} heterotopic bone formation in the paraspinal musculature⁸³ as well as within the neural foramen resulting in recurrent nerve root symptoms,⁸⁴ and vertebral osteolysis up to a rate of 5.8%.⁸⁵ Others have documented subsidence, resorption of bone, and interbody cage migration associated with its use.⁸⁶ In 2011, the use of rhBMP-2 in spine surgery received significant attention,

as Carragee et al. performed a systematic review to compare conclusions regarding the safety and related efficacy published in the original rhBMP-2 industry-sponsored trials and subsequently available FDA publications and databases.⁸⁷ They found an estimated adverse rate associated with the use of rhBMP-2 in spine surgery of 10–50% depending on the approach. Anterior cervical fusion has a 40% greater risk in the early postoperative period while anterior lumbar interbody lumbar fusion rates of implant displacement, subsidence, infection, urogenital events, and RE were listed to be higher than controls. They mentioned all of the complications discussed in the first portion of this paragraph associated with posterior lumbar interbody fusion and found the risk of adverse effects associated with the use of rhBMP-2 in posterolateral fusions to be equivalent to or greater than iliac crest bone graft harvesting. In addition, the most alarming documentation was that higher doses of rhBMP-2 were associated with a greater apparent risk of new malignancy in a location other than the spine itself where the rhBMP-2 was implanted. The group's review of data suggested possible study design bias in original trials, and the risk of adverse events associated with rhBMP-2 being 10–50 times the original estimates reported. Since this study publication, several others have examined the risk of malignancy with the use of rhBMP-2. Devine et al. performed another systematic review of five published peer-reviewed studies and two FDA safety summaries that reported the occurrence of cancer in patients treated with spinal fusion using either rhBMP-2 or rhBMP-7.⁸⁸ This risk of cancer was the same in both rhBMP-2 and control groups of 0.7%. Off label use of rhBMP-2 for posterolateral fusion was associated with a slightly higher risk of cancer compared with controls in three RCTs at 5% using 40 mg of BMP-2 compared with 1% in the control group. The two RCTs that evaluated rhBMP-7 reported cancer risk of 13% and 6% in those who received the product versus 8% and 0% in the control groups; however, these differences were not statistically significant. Thus, the conclusion was that risk of malignancy may be dose dependent and further evaluation was needed. In a study of the use of high dose BMP (greater or equal to 40 mg) of 502 spine cases, Mesfin et al. found a cancer prevalence of 3.4% but did not find a correlation between dosage and cancer and in fact found a negative correlation coefficient of -0.05 , which would incorrectly indicate a protective effect against cancer.⁸⁹

Following the rising concern about the safety and effectiveness of the use of rhBMP-2 in spine surgery, the manufacturer of the product Infuse containing rhBMP-2

provided Yale University a grant to conduct two fully independent third-party systematic reviews of rhBMP-2. This project was termed YODA, or Yale University Open Data Access. These results were published in June 2013. The first site, Oregon Health and Science University, found that rhBMP-2 and iliac crest bone graft were similar in overall success, fusion, and other effectiveness measures and in risk for any adverse event for lumbar spine fusion.⁹⁰ With respect to ALIF, rhBMP-2 was associated with nonsignificantly increased risk for RE and urogenital problems, while for anterior cervical spine fusion, there was an increased risk of wound complications and dysphagia. At 24 months, cancer risk was increased with rhBMP-2, with a risk ratio of 3.45, but event rates were low and the type of cancer was heterogeneous. Importantly, they concluded rhBMP-2 has no proven clinical advantage over bone graft and may be associated with important harmful effects, making it difficult to identify clear indications for its use. The second site, University of York, in the United Kingdom, found that at 24 months, ODI scores were 3.5% better with rhBMP-2 than with ICBG, and radiographic fusion was 12% higher.⁹¹ Pain and cancer incidence were more common than with rhBMP2 use, with a relative risk of 1.98, but there was overall a small number of these events. Thus, evidence of increased cancer incidence is inconclusive.

Today, the use of rhBMP-2 is severely limited compared with its use in the past. The FDA approval remains for ALIF with BAK cages. It remains critical for spine surgeons to deliver clear information regarding safety and effectiveness of rhBMP-2 prior to its clinical use in patients.

Alternative osteobiologics to BMPs include mesenchymal cells and demineralized bone matrix. Early studies indicate that products such as OsteoCel Plus (Nuvasive: San Diego, CA), an allograft bone matrix containing mesenchymal stem cells and osteoprogenitor cells combined with demineralized bone matrix and cancellous bone, may be appropriate substitutes for iliac crest autograft.⁹² Randomized controlled trials need to be conducted with a focus on both fusion rate and safety profiles prior to widespread use.

Adjacent Segment Degeneration

Lumbar fusion has long been the standard for the treatment of chronic low back pain thought to be secondary to lumbar degenerative disc disease. However, a major concern that has developed regardless of technique or method chosen to establish the fusion is adjacent segment degeneration or disease (ASD). This was pointed out as early as 1963, by Harris, in which he noted acquired spondylosis as

a sequel to spinal fusion.⁹³ Adjacent segment disease refers to degenerative processes such as disc herniation, disc degeneration, instability, spinal stenosis, facet degeneration, and deformity that are known to occur after fusion, most commonly at the immediately adjacent functional spinal unit; however, these can also occur at levels not immediately adjacent.⁹⁴ There are various theories as to how this process occurs. Some advocate that it is the natural history of the lumbar spine as it ages that is primarily responsible for this phenomenon. Others, such as Cunningham et al., have shown in biomechanical cadaveric models that instrumented fusions can change the intradiscal pressure present in adjacent levels, which in turn is hypothesized to serve as the impetus for altered metabolic change and thus predisposition to degeneration.⁹⁵ The third proposed mechanism is that the disruption of anatomy of the adjacent level occurs during the initial surgery itself, thus altering the rate at which adjacent levels degenerate.

Both Penta et al. and Wai et al. have used MRI to study disc degeneration 10 and 20 years, respectively, after ALIF, and concluded that individual characteristics of patients or constitutional factors may be more so responsible for the presence of degeneration than increased biomechanical stress above the fusion.^{96,97} Wai documented 74% degeneration in adjacent levels and advanced degeneration in 31%, but found no association between function and the level of degeneration.⁹⁷ Interestingly, 18% of advanced degeneration cases were located at level not immediately adjacent, highlighting the roles of aging or preexisting degeneration.

Wang and Ghiselli studied ASD both cephalad and caudad to the fusion segment and established a predictive rate of 16.5% at 5 years and 36% at 10 years of symptomatic adjacent level disease.⁹⁸ More recently, Lawrence et al. performed a systematic review in which they documented a mean annual incidence of clinical adjacent segment pathology of 0.6–3.9%.⁹⁹ Through their review they identified strong levels of evidence that age >60 years is a significant risk for the development of adjacent segment pathology. Other potential factors that were supported by statistical analysis of combined data that may lead to ASD are preexisting facet degeneration at the time of surgery, degenerative disc disease within the lumbar spine, multi-level fusions, ending a fusion construct at L5, a laminectomy adjacent to a fusion, and excessive distraction across the disc space during a posterior interbody fusion.^{99,100} The integrity of the posterior ligamentous complex has been

postulated to be responsible for lower incidence of ASD in those who undergo ALIF versus those who receive a complete laminectomy during a posterior fusion.^{101,102}

Motion preserving technologies have since been developed with the goal of lowering the incidence of ASD after surgical intervention. These designs hinge on the idea that retaining motion at the indicated segment would less so alter the mechanical environment of adjacent levels. For the purpose of treating degenerative disc disease, motion sparing devices include pedicle-based dynamic stabilization systems, total disc arthroplasty (TDA), and nucleus replacement.

Pedicle-based Dynamic Stabilization (PBDS) Systems

In keeping with preservation of motion within the lumbar functional unit, pedicle-based dynamic stabilization systems were developed to provide soft tissue stabilization while in the long term allowing retention of mobility. They are thought to reduce pain in the setting of degenerative disc disease by unloading the facet joints and the disc. The first PBDS design was developed in Europe and was called the Graf system.¹⁰³ This device utilizes looped 8 mm braided polyester bands instead of rods. Once the pedicle screws are in place, the bands are connected under an applied compressive force similar to the process in ligamentoplasty. The goal was to immobilize the spine in lordosis, compress the posterior annulus, and temporarily stabilize the spine while allowing return of motion or relaxation over time. Hashimoto conducted a 3.5-year follow-up on Graf ligamentoplasty performed for degenerative conditions with minimal instability and also noted preservation of lordosis, significant improvement in VAS scores, but significant loss of preoperative range of motion.¹⁰⁴ Kanayama reported a 10-year follow-up for 43 patients who had Graf ligamentoplasty for various degenerative pathologies.¹⁰⁵ They found a maintenance of lumbar lordosis, flexion–extension motion of approximately 4°, and a 7% ASD incidence.

The Dynesys system was the next to follow and consists of stabilization of pedicle screws by polyester cords that connect the screw heads through a hollow spacer. While the Graf system significantly limited flexion and created excessive posterior annulus compression, the Dynesys system has a push–pull relationship between the spacer and the polyester cord that, respectively, resist

Fig. 78.5: NFlex: A 53-year-old patient with degenerative disc disease at L3-L4 treated with a pedicle-based dynamic stabilization system at 2 years postoperative demonstrating retained motion on flexion–extension lumbar radiographs.

compressive and flexion movements. Again, the goal is to reduce loading of the disc and preserve long-term motion. Studies that have compared segmental fusion to nonfusion techniques with Dynesys such as that by Cakir et al. have found limited preservation of motion and, therefore, recommend against Dynesys implementation.¹⁰⁶ Grob et al. found a 19% revision rate at 2 years,¹⁰⁷ while Bothmann et al. found significant complications after use of this system with a revision rate as high as 28%.¹⁰⁸ Gédet et al. argue that the assumption that a device such as Dynesys that is compliant in bending and allows substantial intersegmental motion is not well supported because the device is not operating near the natural center of rotation of the intervertebral disc.¹⁰⁹ Jahng et al. conducted a comparison study between various PBDs systems including Dynesys, NFlex, PEEK, and the conventional titanium rod, using a validated finite element analysis model.¹¹⁰ They determined that all of the systems have a limited range of motion compared with the intact spine; however, NFlex had a center of rotation closest to the intact and had the highest range of motion preserved (Fig. 78.5). With the lack of RCTs showing favorable superiority with the usage of the dynamic systems, there is a void of high level data to support their routine usage.

Total Disc Arthroplasty

Total disc arthroplasty aims to replace the disc with a mechanical device that closely replicates the range of

motion of the native state of a functional spinal unit. In the setting of discogenic back pain, the offending disc material is removed, thereby alleviating pain, and the implanted device maintains disc height and lordosis thus affording stability of the spine segment. No additional bony healing is necessary as is the case in a fusion. The total disc replacement (TDR) is patterned after total hip and knee arthroplasty with the use of metal and polyethylene components to establish bearing surfaces. In the United States, two devices are currently approved for implantation including the SB Charite III (DePuy) and the Prodisc-L (Synthes: West Chester, PA). Several IDE trials are ongoing with other TDA devices (Figs. 78.6A and B).

As is the case with performing a fusion in the lumbar spine, patients must be carefully selected to undergo lumbar disc arthroplasty. In fact, the criteria are more stringent than a fusion, as the patient must have isolated discogenic pain in the absence of any level of instability, radiculopathy, stenosis, osteoporosis, scoliosis, and, in particular, facet arthropathy. The technique for disc arthroplasty is similar to that of an ALIF as an anterior approach is utilized. Once the disc is removed and endplates are prepared, the surgeon must ensure the posterior annulus fibrosus is released for correct positioning of the device. Depending on the exact design of the prosthesis, it may be necessary to create a keel in the endplates.

Figs. 78.6A and B: Total disc arthroplasty: These images demonstrate a total disc replacement with a Prodisc-L (Synthes).

Initial studies with TDA sought to prove at a minimum, noninferiority to outcomes obtained by lumbar interbody fusion. Guyer et al. reported on a 5-year follow-up study to the initial 2-year follow-up on the safety and effectiveness of the Charite artificial disc with comparison to ALIF with BAK cages and iliac crest autograft.¹¹¹ They demonstrated noninferiority of the Charite in a prospective randomized multicenter fashion, with no statistical differences in clinical outcomes in the two groups, and the Charite retaining 6° on average for range of motion versus 1° for the ALIF group. In addition, Guyer et al. reported a greater rate of employment and lower rate of disability in comparison with the fusion group. Similarly, Zigler et al. performed a prospective randomized multicenter FDA IDE trial on Prodisc versus circumferential arthrodesis for a single level.¹¹² His group also demonstrated noninferiority with this device as there was no statistically significant difference in outcomes at 5-year follow-up and range of motion was retained within normal range. Zigler et al. noted that reoperations were lower in the disc replacement group (8% versus 12% among fusions). Thus, in comparing both the Charite and the Prodisc to fusion, these TDRs have been deemed as reasonable and safe alternatives.

Adjacent segment disease has been studied after TDR. In the same FDA IDE cohort cited in the Zigler study above, it was found that 9% of the TDR patients developed ASD, whereas 29% of the fusion patients did.¹¹³ Concordantly, 2% of the TDR patients underwent revision or additional surgery, while 4% of the fusion patients did. This difference was not found to be statistically significant; however, the

lower rate of ASD with TDRs can be advantageous in the setting where patients would otherwise require a multi-level fusion secondary to asymptomatic or subacute levels of degenerative changes in adjacent discs. Shorter term 2-year follow-up studies comparing ASD after TDR with control patients who received rehabilitation have not demonstrated a difference in incidence of ASD, indicating that perhaps at 2 years natural history has only played an effect, while with longer term follow-up the difference between fusion and TDR may become amplified with the interplay of natural history and biomechanical stressors.¹¹⁴ Interestingly, the TDR patients in Hellum's study did have a higher incidence of facet arthritis (34%) than controls who underwent rehabilitation (4%) at 2-year follow-up. Park et al. found a 29% incidence of facet arthritis at 26-month follow-up with Prodisc-L implants,¹¹⁵ while Shim et al. in a comparative study between Prodisc-L and Charite found an incidence between 32% and 36% at 3 years follow-up.¹¹⁶ Development of facet arthrosis could be one of the important variables that alters the stresses seen at adjacent levels.

Given that TDA may lead to a lower incidence of ASD despite similar functional outcomes in FDA trials at 5 years, longer term follow-up must be analyzed to ensure that there is no deviation in this performance down the line. Currently, most data is presented at a maximum of 5-year follow-up. Outside FDA trials, there is some indication that a difference may exist even at 5 years, favoring TDA. Sköld et al. conducted an RCT with data from the Swedish Spine registry of TDR versus posterior lumbar fusion.¹¹⁷ Back pain assessed with validated outcome scores including

VAS and ODI was significantly better after TDR at 1 year, no different at 2 years, and the statistically significant difference reappeared at 5 years. They also found no difference between complications and reoperations between the two groups.

To conclude that TDA outperforms fusion also requires demonstration that it is more cost-effective in the management of refractory discogenic pain. Levin et al. looked at raw implant cost with one- and two-level TDA with Prodisc-L versus circumferential fusion and found that the difference was minimal with a single level at \$13,800 for TDA and \$13,990 for fusion.¹¹⁸ However, total charge for TDA was \$35,592 versus \$46,280 for fusion as operating room costs differed at \$12,000 versus \$18,950, operating time was 185 versus 344 minutes, blood loss was 412 versus 794 mL, and mean length of stay was 4.32 versus 4.78 days, all in favor of TDA. When two-level procedures were analyzed, costs were similar. Fritzell et al. assessed the cost-effectiveness of TDR (Charite/Prodisc/Maverick) when compared with posterior lumbar interbody fusion with pedicle instrumentation at 2 years in an RCT.¹¹⁹ Their analysis included cost to society in which there was no difference, while the cost to health care was significantly less for TDR. However, when total gain in quality adjusted life years was considered, they were unable to determine which procedure was greater at 2 years and asserted that longer term follow-up is necessary to complete this analysis. Therefore, selection of TDA over fusion is still debatable.

Another important consideration in the adoption of TDA as a safe alternative to fusion is the complication profile. Though the goal of TDR is to retain motion of the lumbar segment there have been reports of heterotopic ossification (HO) occurring at the level of surgery and in some cases, this has even lead to spontaneous fusion. In 2003, McAfee et al. developed a five-grade classification system for HO formation around a disc prosthesis.¹²⁰ The important classes to distinguish between are class II and III, as in the latter, the range of motion of the vertebral endplates is blocked by the formation of HO, thus limiting flexion, extension, or lateral bending. Tortolani et al. performed a prospective, randomized study of 276 patients who underwent a CHARITE disc replacement and found a low incidence of HO of 4.3% at 2 years.¹²¹ None of these cases had a difference in range of motion or clinical outcome from those that did not have any evidence of HO. Park et al. evaluated 65 patients with 82 segments of TDA including mostly Prodisc and some Charite prostheses and reported an incidence of 30.5% at 17 months. Only

6% demonstrated class III HO. Despite their significantly decreased motion, the outcome scores for these patients were not significantly different from those who did not have any HO. Most of the HO was present in the anterior and posterior aspects of the prosthesis. Huang et al. looked at the risk factors for HO so as to develop preventive strategies against this complication.¹²² In examining 78 levels in 65 patients, they had an incidence of 13% HO, with two cases that were class III at 2 years that eventually went on to class IV (ankylosis) at 6 years. Risk factors identified included preoperative annulus ossification, bony endplate injuries during preparation for and insertion of prosthesis, malpositioning of device, and subsidence of the prosthesis.

Other notable complications that can occur include implant loosening, malposition, displacement, subsidence, early wear, and infection.¹²³ Punt et al. used a computer-generated 3D bone-implant model to determine that a reduced risk of subsidence is correlated to the implant covering >62% of the bony endplate.¹²⁴ Avoidance of undersizing may therefore reduce the risk of subsidence. Punt and colleagues also compared clinical outcomes for different revision strategies for the failure of TDA at an average of 4 years follow-up.¹²⁵ Eighteen patients underwent a posterolateral instrumented fusion without removal of the prosthesis while 21 patients had the prosthesis removed, defect filled with bone graft strut, and instrumented posterolateral fusion performed. Both procedures showed clinical improvement with no significant difference between VAS and ODI scores. Given the significant potential for injury associated with the removal and the similar outcome between the two procedures, the risk of removal should be weight against retention of device and fusion. Wear, oxidation, and, in particular, rim impingement of ultra-high molecular weight polyethylene TDRs have been observed during revision surgeries. Baxter et al. determined that severe rim impingement can increase the production of biologically relevant particles from motion-preserving lumbar TDR components,¹²⁶ while Lebl et al. found that impingement was most commonly found in extension as evidenced by metallic endplate burnishing in Prodisc-L devices.¹²⁷ Disc height distraction, anterior-posterior position, implant lordosis, and sagittal orientation all play a significant role in the occurrence of impingement and should be optimized to reduce enhanced wear and generation of particle debris.¹²⁸ Like their counterparts in hip and knee surgery, TDA wear can in turn lead to osteolysis and therefore long-term follow-up of these patients is recommended.¹²⁹

Recently Jacobs et al. published a Cochrane review of 7 randomized controlled trials on lumbar total disc arthroplasty.¹³⁰ As mentioned above, the focus of many studies has been to compare the effectiveness and safety of total disc arthroplasty to fusion. This study also found clinical outcome scores to be slightly higher in disc arthroplasty though not exceeding the clinically relevant confidence interval. Thus, adoption of total disc arthroplasty as the definitive alternative to fusion for treatment of chronic discogenic pain was cautioned against. Instead, the study advocates for further scrutiny of longer term followup data. The need is still present to demonstrate a significant advantage of disc arthroplasty over fusion to revolutionize treatment paradigms.

Nucleus Replacement

Along the spectrum of degenerative disc disease, one of the earlier signs is a loss of hydration within the nucleus pulposus. In light of this, one of the newer therapeutic alternatives to lumbar fusion is prosthetic nucleus replacement. The aim of these devices is multifold: restore intervertebral height while allowing for retention of the outer annulus fibrosus, restore the normal endplate load redistribution, recreate the intradiscal hydraulic pumping mechanism that in the native state allows for nutrient delivery and metabolic waste removal, be a minimally invasive biocompatible option, and finally permit retention of normal range of motion.

Basic requirements for implantation of a nucleus prosthesis include normal integrity of the annulus fibrosus so as to provide containment and minimize migration of the device. In addition, depending on the design of the introduction of the device, annulotomy may be required and therefore full healing potential is optimal. Contraindications include osteoporosis as well as significant degenerative changes within the endplates, as endplate arterioles must be capable of metabolic exchange. Optimal disc height is a minimum of 5 mm. In addition, these requirements also minimize the risk of subsidence after implantation.

The first nucleus replacement was designed by Dr Fernström in 1966. This was a stainless steel ball with 16 mm diameter and significant problems were encountered with prosthetic migration and subsidence.¹³¹ Since then, various models have been developed for nucleus replacement. In 1988, the prosthetic disc nucleus (PDN) was introduced by Dr Ray.¹³² This consisted of two disc cylinders oriented anterior-posterior along the plane of the disc and they were filled in situ with hydroscopic, water absorbing

gel. Clinical trials revealed a 38% revision rate leading device design modification to two transversely oriented units that are tethered by suture and contain hydrogel polymer surrounded by polyethylene jacket. In 2002, Klara and Ray published the success from a clinical trial standpoint with the PDN.¹³³ Several technique notes were made, including the use of a minimal opening in the annulus through which device units were implanted and a series of dilators to help stretch fibers without exceeding their tensile limits, in order to allow for improved healing potential. Four-year follow-up data was presented and showed a significant reduction in symptoms, Oswestry score improvement to 10% (minimal disability), mean Prolo score improvement to excellent, and disc height improvement to a mean of 1.8 mm. In review of the 423 PDNs that had been implanted since 1996, 10% had been explanted with a surgical success rate of 90%. More recently, Selviaridis et al. reported on long-term outcomes of PDN implantation in 10 patients.¹³⁴ Significant improvements in Oswestry, Prolo, and VAS scores were documented, while treated disc height was shown to increase postoperatively and be maintained. No significant modifications were found in the disc height at the level above, and lumbar spine range of motion was restricted in relation to normal but still allowed for considerable mobility.

In terms of approach to the disc for insertion of prosthetic nucleus, the traditional method has been a laminotomy as performed in a microdiscectomy to be able to access the disc space. Bertagnoli has developed the anterior lateral transpsoatic approach (ALPA) for PDN implantation.¹³⁵ Much like a lateral approach for fusion, the disc is accessed via the retroperitoneum through the psoas. An annulus flap is created to perform nucleotomy and once the device is inserted, the annulus flap is replaced and sutured in place. In his review of the use of PDN through ALPA, Bertagnoli noted lower incidence of migration.¹³⁶ In addition, he noted that use of a softer hydrogel, which absorbs 80% of its weight in water (as opposed to prior formulations which absorbed 68%), resulted in a decrease in endplate remodeling—a complication that can lead to reduced disc height and necessity for revision procedures.

An additional nucleus replacement that has recently been published is the NUBAC system.¹³⁷ This is the first articulating nucleus prosthesis that is constructed from PEEK with an inner ball/socket articulation. Balsano et al. reported on 39 patients that underwent implantation of this device through a posterior approach or extreme

lateral approach. With 2 year followup, there was a significant decrease in VAS from 71 to 14 and ODI from 58% to 14%; additionally, there was considerable symptomatic improvement in those patients with chronic low back pain.

There are a number of other nucleus replacement devices being evaluated for potential clinical use both in the United States and in Europe. Focus is also being placed on the development of injectable hydrogels that can minimize trauma associated with access to the disc and serve as a scaffold on which to develop nucleus pulposus tissue or a means by which to deliver mesenchymal cells to the nucleus pulposus for tissue engineering purposes.

CONCLUSION

In this chapter, multiple methods of surgical treatment were reviewed for the management of lumbar degenerative disc disease. Surgeons must continue to rely on level I evidence to educate patients and make clinical decisions that best suit patient desires for functional outcome in light of their medical comorbidities. Though the gold standard for surgical management remains fusion, future research will continue to focus on alternative methods of treatment that may be superior to the current standard.

Nonoperative Treatment of Lumbar Stenosis

Keya Mao, Peng Li

Snapshot

» Major Types of Spinal Stenosis

» Therapeutic Options for Lumbar Stenosis

INTRODUCTION

Lumbar spinal stenosis (LSS) is one of the most common reasons why patients in their middle and later years seek a consultation with a neurosurgeon or spine surgeon. Lumbar spinal stenosis is related to degeneration of the spine and usually becomes significant in the fifth decade of life and extends throughout every subsequent age group. Most patients first visit their doctor with symptoms of spinal stenosis at about 60 years of age or so. In lumbar stenosis, the spinal nerve roots in the lower back are compressed, or choked, and this can produce symptoms of sciatica-tingling, weakness, or numbness that radiates from the lower back into the buttocks and legs especially. In rare cases, LSS can produce severe persistent disabling pain and even weakness in the legs. Most cases of stenosis in the lumbar spine, however, produce pain that radiates into the legs on walking but is relieved by sitting. This is called claudication, which can also be caused by circulatory problems in the legs. Depending on the severity of the symptoms, spinal stenosis can often be managed through nonoperative treatments. This is more effective in LSS patients with mild or occasionally moderate pain.¹⁻³ Naturally, nonoperative therapy is the treatment of choice in patients without motor disturbances and/or bladder or intestinal dysfunction.⁴⁻⁷ Nonoperative treatment options include physiotherapy and exercise, epidural steroid injections, massage therapy and other analgesic or

anti-inflammatory medications, and these are usually prescribed in combination with other therapies.⁸⁻¹⁶

Lumbar spinal stenosis is typically secondary to arthritic changes in the facet joints or discs, congenital stenosis, or instability (spondylolisthesis).

MAJOR TYPES OF SPINAL STENOSIS

Foraminal Stenosis

As the nerve root is about to leave the canal through the lateral foramen, a bone spur that has already developed from a degenerating disc can press on that nerve root. This type of stenosis is sometimes termed lateral spinal stenosis, which is by far the most common form of spinal stenosis. Seventy-two percentage cases of foraminal stenosis occur at the lowest lumbar level. With this type of lumbar stenosis, the emerging nerve root is trapped. The emerging nerve root is trapped in an up down manner from a collapsed disc and its associated disc osteophyte complex.

Central Stenosis

A choking of the central canal in the lumbar area can compress the sac containing the horse's tail bundle of loose nerve filaments. Central spinal stenosis is more common at the second from the lowest lumbar spinal level and higher, and is largely caused by a bulging of the disc margin plus a major overgrowth or redundancy of a

ligament that helps protect the dura. This overgrowth is caused by segmental instability, usually from a degenerating disc between adjacent vertebrae. The ligament arises from under the flat laminae of the vertebrae and the inside part of the facet joint.

THERAPEUTIC OPTIONS FOR LUMBAR STENOSIS

Education

Providing patients with information about back anatomy causes and natural history of lumbar stenosis and advice about activity and exercise are important aspects of management. Education is helpful in setting realistic expectations for the outcome of treatment. Information may be provided by individual face-to-face contact with a physician or nurse, by an information booklet or by group sessions. Patients should be encouraged to identify activities and situations that cause discomfort and solve problems with the therapist to determine appropriate movement strategies and easing positions. Helpful advice may include items such as temporary avoidance of prolonged overhead activities, temporary avoidance of prolonged axial loading and methods of self lumbar-pelvic flexion and/or rotational stretching techniques for pain control during standing, sitting, and lying. Basic body mechanics are taught to patients with LSS, and they should be advised to change position frequently, know and respect their current limits, and pace activities such as housework and yard work. In addition, an explanation of the current concepts of pain as an “output and not an input” can help reframe the patient’s relationship with the problem and motivate them to increase their functional status. Finally, patients should be aware of the natural course of this condition. Despite the recommendations patients receive from non-medical sources, the majority of those with LSS do well over time, with their condition either remaining the same or improving with no intervention. Also, that long-term results are often no different when comparing those patients who received surgery for LSS and those who were treated nonsurgically.

Rest

In most patients with lumbar stenosis, bed rest for > 1 or 2 days should not be recommended. The primary negative consequence of inappropriate bed rest is delay in return-

ing to normal activities. In addition to delay in recovery, other potential adverse consequences of bed rest include rapid loss of muscular strength at a rate of approximately 5% per week, bone loss at a rate of nearly 1% per week, general deconditioning and increased social isolation and depression.

Physical Therapy

Daily lifestyle adjustments, back training, exercise programs to stretch, strengthening the lumbar region, and general conditioning exercises prescribed alone or together with physical therapy yield good clinical results.¹⁷⁻²⁹ Physical therapy is the foundation of nonsurgical treatment. The aim is to strengthen the abdominal and back muscles, preserve motion in the spine, and improve overall fitness. Stretching, strengthening and aerobic activity (e.g. bicycling) are usually recommended. Abdominal corsets or braces can help ease pain, but they may also weaken postural muscles, so the patient is advised not to wear a corset or brace for more than a few hours a day.³⁰ The stretching program should include stretching of the hip flexors, hamstrings, and paraspinals. The strengthening program should focus on the abdominal and gluteal musculature. A posterior pelvic tilt can be included in many of the stretching/strengthening exercises for postural education. Unloading activities are often used including traction, weight-supported treadmill walking, and water-based therapy. Other techniques used by therapists include spinal mobilization, proprioceptive neuromuscular facilitation techniques, neuromuscular massage, ergonomic training, and general reconditioning. Conditioning exercises can be designed to avoid pseudoclaudication. Walking on an incline is often better tolerated than level walking. Stationary biking is usually comfortable.

Swimming is also a good alternative; sidestroke is sometimes better tolerated than breaststroke or freestyle that requires lumbar extension.³¹ Physical therapy includes both passive and active treatments. Passive treatments help relax the body. They also prepare the body for therapeutic exercise, which is the active part of physical therapy. Physical therapist can give passive treatments such as deep-tissue massage: this technique targets chronic muscle tension in the lumbar spine that perhaps builds up as a result of daily life stress. The therapist uses direct pressure and friction to try to release the tension in the soft tissues (ligaments, tendons, muscles).

Hot and Cold Therapies

By using heat, the physical therapist seeks to get more blood to target the area because an increased blood flow brings more oxygen and nutrients to that region that helps the body to heal. Cold therapy slows the circulation, helping to reduce inflammation, muscle spasms, and pain. Your physical therapist will alternate between hot and cold therapies.³²⁻³⁴

Exercises

Exercises may include the use of an exercise bicycle and/or brief walks. Walking is a suitable exercise for spinal stenosis patients. Swimming is also an ideal exercise because it exercises all the back muscles in a safe, supportive environment. The water supports the weight well, which means that there is less weight on the patient's back. One could also combine walking and swimming and do some water walking. Gentle stretches that relieve the pressure on nerves are a great help too. Because spinal stenosis decreases the space that the spinal cord and nerve roots go through, exercises that open up that space are recommended. Generally, flexion exercises are helpful in alleviating the symptoms of spinal stenosis. Although a suitable program of spinal stenosis exercises may be helpful in the hands of a good physical therapist, it is not curative. Even though stenosis exercises are not a cure, however, it is very important for patients to remain active and not additionally debilitated from inactivity. Therefore, appropriate spinal stenosis exercises are a key part of any treatment program. Progressive exercise may help increase lumbar-pelvic muscular stabilization and maintain better posterior pelvic tilt. It may also improve cardiovascular conditioning and other factors that enhance soft tissue function. Studies on exercise treatment particularly emphasize the importance of flexion exercises and recommend the addition of general conditioning exercises.³⁵⁻³⁷

Epidural Injections

Epidural interventions are one of the most commonly performed interventions for managing LSS.³⁸⁻⁵⁸ The use of steroid injections is based on the belief that pain symptoms result from inflammation at the interface between the nerve root and the compressing tissues.^{59,60} The purpose of injecting corticosteroids is to reduce inflammation, and these injections are frequently combined with local anesthetics for pain relief. In addition to therapeutic

treatment, epidural steroid injections are also frequently used for diagnostic purposes.⁶¹ There are three major types of epidural steroid injections performed for LSS: the traditional translaminar injection, the caudal injection, and the transforaminal injection.⁶²⁻⁶⁸ However, transforaminal epidural injections are also associated with substantial risk compared to either caudal or interlaminar epidural injections.⁶⁹⁻⁸¹ Although there is no consensus regarding frequency, most practitioners recommend that individuals not receiving substantial relief with the first injection undergo up to two repeat injections at 2–4-week intervals. A number of trials have looked at the efficacy of steroid injections. Although there are mixed results, the majority of studies have unfavorable long-term results. Rosen et al.⁸² did a retrospective study of 40 patients with LSS who received translaminar epidural injections; 60% of those patients reported relief at 2 months and only 25% had relief at 8 months. Cuckler et al.⁸³ performed a prospective randomized evaluation of a translaminar epidural injection and found that only 2 of 41 patients had significant relief (>75%) at long-term follow-up. Buenaventura et al.⁸⁴ in a systematic review of therapeutic lumbar transforaminal epidural steroid injections, evaluated four randomized trials⁸⁵⁻⁸⁶ based on Cochrane musculoskeletal review group criteria, with criteria of short-term relief as <6 months and long-term relief as >6 months. They showed Level II-1 evidence for short-term relief and Level II-2 for long-term relief in managing chronic low back and lower extremity pain. Normally, patients were administered the first injection by the translaminar or caudal route. The second injection was administered at the level of the most significant thecal sac compression by the transforaminal (specifically epidural and not extraforaminal or nerve root sheath injection) route. The third was administered when needed, according to the physician's discretion.⁸⁷

Ultrasonography is effective for guiding caudal epidural injections. Ultrasound guidance is a rapid and safe means of ensuring that the injection is performed into the epidural space. The lower risk of postlumbar puncture syndrome and the ease of execution may make caudal epidural injection a good method for treatment at the rheumatologist's office.⁸⁸

Massage Therapy

Massage therapy in various forms has been widely used in the treatment of back pain for many years. Massage therapy takes many forms, including classical Swedish,

deep-tissue massage, acupuncture massage, friction massage, myofascial release, and other variations.

Transcutaneous Electrical Nerve Stimulation

Transcutaneous electrical nerve stimulation (TENS) has been used for pain relief for >30 years. As originally conceived, TENS was a noninvasive technique of peripheral nerve stimulation based on the premise that counter stimulation of the appropriate nerve fibers would alter pain perception. The gate-control theory of pain provided the initial theoretical framework for TENS development. As suggested in animal models, high-frequency, low-intensity TENS was believed to stimulate large afferent nerve fibers that activate inhibitory neurons at the local dermatomal spinal cord level, resulting in the inhibition of smaller sensory nociceptive fiber inputs.

Acupuncture and Electroacupuncture

Acupuncture is a centuries-old therapy, rooted in East Asian medicine, which has been increasingly adopted and adapted by Western practitioners. More than 1 million Americans are treated with acupuncture annually for a variety of musculoskeletal conditions, including fibromyalgia and low back pain. Acupuncture and pressure point massage are mildly helpful for LSS, and the benefits last for up to 1 year. Massage appears to be most effective when combined with exercise, stretching, and education.⁸⁹

Electroacupuncture of spinal nerve roots employs a selective spinal nerve block technique for inserting acupuncture needles. After inserting two needles as close as possible to the relevant nerve root under X-ray fluoroscopy, low-frequency electroacupuncture was performed using the needles as electrodes. Under X-ray fluoroscopy, two acupuncture needles were inserted as close as possible to the relevant nerve root, as determined by subjective symptoms, and X-ray, magnetic resonance imaging (MRI), and low-frequency electroacupuncture stimulation (10 Hz, 10 minutes) were performed. Patients received 3–5 once-weekly treatments and were evaluated immediately before and after each treatment and 3 months after completion of the treatment.^{90,91} The relevant nerve root was determined from symptoms, physical findings, and imaging data (plain X-ray, MRI). Using a procedure similar to that used for spinal nerve root block, with the patient in the prone position, two disposable

acupuncture needles (90 mm long, 0.25 mm in diameter, Seirin Co., Shizuoka, Japan) were inserted as close to the relevant nerve root as possible under X-ray fluoroscopy. Low-frequency electroacupuncture was then conducted using the two needles as electrodes (stimulation frequency 10 Hz, stimulation time 10 minutes, stimulation strength at a tolerable level for the patient). The verification of the proximity of the needles to the relevant nerve root was performed by approximate positioning using X-ray and comments by patients where stimulation could be felt in an area supplied by the damaged nerve. Treatment was performed once a week. If symptoms were found to have been completely resolved 1 week after the previous treatment, that day was taken as the final day of treatment, with five being the maximum number of treatments.

Nonopioid Analgesics and Nonsteroidal Anti-inflammatory Drugs

For LSS, medications are not the initial therapy physicians should consider. According to a comprehensive review, at best drugs relieve only about 30% of chronic pain. In older patients, pain medications increase the risk of falls, cognitive deficits, constipation, bladder dysfunction, and adverse drug interactions. Medications are useful but should not be the primary intervention for spinal stenosis.⁹²

Anti-inflammatory medication (such as aspirin or ibuprofen) may be helpful in treating spinal stenosis. Some physicians recommend a multiple B-complex vitamin with 1,200 µg of folic acid daily, but this has not been substantiated in the medical literature as an effective treatment for stenosis. In patients with less severe symptomatology, nonsteroidal anti-inflammatory drugs (NSAIDs) were administered for a 4–6 week period of time and occasionally repeated. Most patients with significant radiculopathy were administered one course of oral corticosteroids on a 7-day tapering schedule. Acetaminophen is the first-line therapy because of its high safety profile. Nonsteroidal anti-inflammatory drugs provide similar analgesia but have significant gastrointestinal and renovascular adverse effects.^{93,94}

Nonsteroidal anti-inflammatory drugs have anti-inflammatory and pain relief properties that make them attractive for the treatment of spinal stenosis, but are equally efficacious compared to acetaminophen, which only provides pain relief.⁹⁵ Cyclo-oxygenase (COX)-2 selective agents had been recommended for older individuals because of fewer serious gastrointestinal side effects. However,

recent evidence of increased cardiovascular risk especially associated with long-term use in higher-risk individuals makes these agents unattractive in patients with spinal stenosis.⁹⁶ Narcotics may be helpful when used for short periods on a regular basis in individuals with severe pain, including radicular pain associated with spinal stenosis that is not controlled by NSAIDs or acetaminophen. For patients with persistent symptoms, short-acting, and long-acting opioids are often used despite very limited evidence of efficacy. Few authors have compared the risks and benefits of opioids with other medications when used on a continuous basis for a longer period of time, especially in older individuals who may be at a greater risk of experiencing side effects.^{97,98}

Muscle Relaxants

Muscle relaxants make less theoretical sense, given the degenerative nature of LSS, but again there are no trials demonstrating the superiority of other listed medications.⁹⁹ Although the precise anatomic source of lumbar stenosis is frequently ill defined, muscle sprain or strain is believed to be responsible in many patients. All muscle relaxants provide similar short-term improvements in pain and function, but there is no unequivocal data to support their long-term use to treat chronic low back pain. Sedation is a common adverse effect and continuous use of benzodiazepines and carisoprodol (Soma) carries the risk of dependency.¹⁰⁰ Given the underlying degenerative process thought to be associated with the development of symptomatic spinal stenosis, the use of muscle relaxants (such as diazepam or cyclobenzaprine) in spinal stenosis makes less inherent sense, although there is no evidence arguing that the relative risks and benefits favor other agents. For patients without severe pain, muscle relaxants and narcotics offer few advantages and have more side effects.¹⁰¹

Antidepressants

Antidepressant therapy is appropriate for patients with depressive symptoms that accompany the chronic pain, but its value for patients who are not depressed is unproven. When used, antidepressants with combined serotonergic-noradrenergic effects, such as the tricyclic antidepressants (TCAs), have more consistent antinociceptive effects than agents that only affect serotonergic systems. Finally, a randomized study of nasal calcitonin was ineffective compared with a placebo for patients with spinal stenosis. This study represents what will hopefully be an increased number of high-quality controlled trials of treatments

for this disorder.^{102,103} Tricyclic antidepressants are an option in the algorithm to manage subacute or chronic lower back pain. Nortriptyline was selected for patients with sicca symptoms. The dose was increased weekly by 10 mg until the patient was satisfied with the level of pain control or side effects were noticed. The TCA dose in patients with clinical improvement ranged from 10 to 100 mg. More than half (11, 55%) of the patients who reported clinical improvement stayed on the initial dose of 10 mg daily of either amitriptyline or nortriptyline, with good results.

INTRODUCTION

Lumbar canal stenosis is an established spinal pathology and the first description of the narrow spinal canal dates back to 1803, when it was described by Antoine Portal.¹ However, the most advances in the diagnosis and management of spinal stenosis have taken place in last 50–60 years. Etiologies for lumbar canal stenosis vary; however, it can generally be grouped into degenerative, congenital, or metabolic disorders. Degenerative spinal canal stenosis is the most common pathological process resulting in the critical narrowing of the spinal canal, which compresses the neural elements. Degenerative stenosis is attributed to the degenerative changes in facet joints, ligamentum flavum, and intervertebral discs. Congenital spinal stenosis occurs because of growth disturbances of posterior elements, resulting in abnormal anatomy and deformities, and can result in symptomatic presentation early in the life.² Bone dysplastic disorders, such as achondroplasia, can result in spinal stenosis because of narrow and short pedicles and medialized facets.³ Some metabolic and storage disorders like Paget's disease and Morquio's syndrome can result in abnormal accumulation of undegraded substances in tissues resulting in narrowing of the space available for the neural elements. In this chapter, we will focus

predominantly on degenerative lumbar spinal stenosis. The purpose of this chapter is to review the pathophysiology, clinical features, indications, surgical techniques, and outcomes for the open surgical management of lumbar spinal stenosis.

PATHOPHYSIOLOGY

The degenerative process generally starts with disc dehydration, disc height loss, and bulging of disc and ligamentum flavum in the canal and, eventually, formation of disc-osteophyte complexes that decreases the volume of the spinal canal.⁴ Loss of normal disc function results in abnormal stress transfer and concentration at facet joints, which causes the thinning of the facet cartilage and subsequent osteophyte formation. With progressive incompetence of the facet joint capsule and disc degeneration, segmental spinal instability can occur and result in varying degrees of “olisthesis” (slippage) of one vertebra in relationship to another. This progression of degenerative changes can result in characteristic anatomic areas of stenosis, which include the central canal, the lateral recess, and neuroforaminal zone. Along with direct compression, local inflammation, neural ischemia, and neuritis are all additional contributors to the pathophysiology of the disease.

Figs. 80.1A and B: (A) Sagittal and (B) axial T2-weighted magnetic resonance imaging (MRI) of the lumbar spine demonstrating central stenosis. Notice the more sagittally oriented facet joint and hypertrophy of the inferior articular facet (asterisk) of the superior vertebra will result in central stenosis (arrows). Notice the presence of high-intensity fluid within the facet joints bilaterally suggestive of fluid and potential facet incompetence, which is confirmed by the presence of subtle grade 1 spondylolisthesis on the sagittal MRI at L4-L5.

Central Stenosis

Anatomically the inferior articular facet/process of the cephalad vertebra lies posteromedial to the SAP of the more caudal lumbar vertebra. Therefore, hypertrophy of the inferior articular facet will classically result more in central spinal stenosis (Figs. 80.1A and B). Classically these patients will present with symptoms of multiple root compression and neurogenic claudication.

Lateral Recess Stenosis

Lateral recess stenosis is also known by several other terms, which include “subarticular stenosis” and “entry zone stenosis.” Anatomically, the lateral recess lies just ventral to the superior articular facet/process (SAF/SAP). Therefore, hypertrophy of the SAF typically results in lateral recess stenosis (Figs. 80.2A and B). Classically these patients will present with symptoms of single root compression and radicular symptoms.

Neuroforaminal Stenosis

Anatomically the neuroforamen is bound anteriorly by the posterior aspect of the vertebral body and intervertebral disc, posteriorly by the pars, and superiorly and inferiorly by the corresponding pedicles. Therefore, the most common causes of neuroforaminal stenosis include advanced disc degeneration and progressive collapse of the

intervertebral disc space resulting in the so-called “up-down stenosis” (Fig. 80.3). However, extruded discs migrating into the neuroforamen and pars defects can also result in neuroforaminal stenosis.

CLINICAL PRESENTATION AND ENTITIES

The clinical symptoms for lumbar spinal stenosis vary from patient to patient and, as discussed above, are related to the area of neural compression. Lumbar central stenosis typically causes the symptoms of neurogenic claudication, while lateral recess and neuroforaminal compression classically result in single nerve root compression (radiculopathy). Classic neurogenic claudication symptoms are described by the patients as numbness, tingling, weakness, and leg heaviness typically reported in the posterior buttock radiating down the posterior lateral thigh.⁵ This should be differentiated from pain radiating in a more specific dermatomal location raising the concern for a concomitant nerve root compression.

Neurogenic claudication is caused by direct compression of the neural vascular supply, which leads to its clinical manifestations. The incidence is predicted to increase as the lifespan of the general population increases. Due to improvements in health care and life expectancy, there will continue to be a larger population of active elderly individuals who are predisposed to developing lumbar

Figs. 80.2A and B: (A) Sagittal and (B) axial T2-weighted magnetic resonance imaging of the lumbar spine demonstrating lateral recess or subarticular zone stenosis. Notice the more coronally oriented facet joints and hypertrophy of the superior articular facet (asterisk) of the inferior vertebra results in lateral recess, or subarticular zone stenosis (arrows). The central canal remains relatively less involved.

Fig. 80.3: Parasagittal T1-weighted magnetic resonance imaging demonstrating foraminal zone stenosis (arrowhead). Notice that loss of the normal perineural foraminal fat at the stenotic level at L5-S1.

stenosis, which is a major cause of impaired quality of life and pain. Up to 25% of the general population has lumbar stenosis over the age of 50 years.

When treating lumbar stenosis, one must have a thorough understanding of the diagnosis, evaluation and pathologic anatomy. As discussed in the previous chapter a course of appropriate nonoperative management should be the first line of treatment. When indicated, operative treatment has been shown to produce significant, long-lasting outcomes.

Table 80.1: Differential diagnosis for lumbar stenosis.

- Peripheral artery disease (vascular claudication)
- Leriche's syndrome
- Hip osteoarthritis
- Lumbar spondylosis
- Diabetic peripheral neuropathy

A thorough clinical history should be taken. Often times, the duration, inciting factors, and pain location can help differentiate lumbar stenosis from other disease processes (Table 80.1). In order to not miss concomitant pathology and to help ascertain where the compressive pathology is affecting the neural elements, a complete motor, sensory, and reflex examination should be undertaken. Attention should be paid to previous scar, sagittal, and coronal alignment. In addition, close attention should be given to the age of the patient and comorbidities, as these affect patient outcomes and risk for complications with surgical treatment.

Neurogenic claudication and back pain caused from lumbar stenosis must be differentiated from vascular claudication or other common diagnoses that cause leg pain (Table 80.1). A classic complaint in patients with lumbar stenosis is posterolateral buttock and leg pain with characteristics of burning, paresthesias, heaviness, or easy fatigue. The pain is mechanical, but unlike vascular pathology, riding a bike or walking uphill will not cause symptoms because the cross-sectional area of the central canal

and neuroforamina is increased with the forward flexion posture. Therefore, neurogenic claudication pain is exacerbated with back extension and alleviated with lumbar flexion, the so-called “shopping cart sign.” Walking downhill is worse with lumbar stenosis, the opposite of vascular claudication.

Vascular claudication due to peripheral artery disease is often accompanied by other physical examination findings. There are skin changes (edema and decreased hair) and diminished peripheral pulses. The symptoms are also relieved by cessation of activity, but forward flexion does not improve the symptoms. Forward flexion and sitting alleviate symptoms in lumbar stenosis due to opening the spinal canal. Vascular disease due to proximal aortoiliac occlusive disease (Leriche’s syndrome) should be considered. Leriche’s syndrome has the triad of buttock claudication, atrophy of the gluteal muscles, and impotence.

Hip arthritis typically presents as anterior groin pain. Typically, this pain can be reproduced with internal and external rotation of the hip, and often times has start up pain and pain at night described as a “tooth ache.” Similar to lumbar degenerative disease, hip arthritis may benefit from localized steroid injections. In this way, a fluoroscopically guided hip injection can be used for diagnostic and therapeutic purposes.

Diabetic or idiopathic peripheral neuropathy can also cause symptoms of leg pain. This pain is usually unrelated to activity and typically involves both lower legs in a stocking glove distribution.

A full discussion of the examination of the patient with lumbar spinal stenosis is beyond the scope of this chapter; however, it can vary to a large degree from patient to patient and is typically unremarkable. Patients may prefer a forward flex posture with aggravation of their symptoms with lumbar extension. While pain and or numbness can be common, motor weakness is relatively uncommon, and typically reflexes are normal. However, in patients with severe stenosis reflexes can be diminished. Provocative tests, such as the straight leg raise is typically negative in degenerative spinal stenosis. Questions in regard to bowel and bladder dysfunction should also be elicited.

It should be noted that a careful upper extremity examination should be undertaken in all patients with lumbar stenosis, because upper motor neuron (UMN) signs such as lower extremity hyperreflexia, clonus, and Babinski’s signs can be absent in patients with severe lumbar stenosis and may only be identified through a careful history and potential presence of upper extremity UMN signs such

Figs. 80.4A and B: (A) Extension and (B) flexion standing lateral radiographs demonstrate the presence of a spondylolisthesis.

as Hoffman’s signs and upper extremity hyperreflexia. In these patients, advanced imaging of the cervical spine should be considered, and depending on the findings, may warrant addressing the cervical stenosis prior to any lumbar interventions.

IMAGING

Imaging should begin with upright anteroposterior, lateral and flexion–extension views of the lumbar spine. Stress views or lumbar spine flexion/extension views (Figs. 80.4A and B) help in defining any evidence of instability or spondylolisthesis, as the presence of a spondylolisthesis could warrant fusion of the unstable segments in addition to the decompression. If there is scoliosis or concerns of a significant sagittal plan deformity, a full-length standing scoliosis film will give the surgeon an idea of the sagittal and coronal alignment of the spine. Assessment of the pelvic incidence, pelvic tilt, sacral slope and facet orientation at the involved level is also advised if there is consideration of more than just a decompression procedure.

Magnetic resonance imaging (MRI) is the diagnostic modality of choice to give further detail into the degrees of stenosis. The nerve roots tend to sediment in the posterior half of the sac on a supine MRI axial image, and the absence of normal sedimentation of the roots in the presence of central canal stenosis, a “sedimentation sign,”^{6,7} is reported to correlate with central stenosis in 54% of the patients. It is reported to be positive in 82% of cases with dural sac cross-sectional area of <80 mm.⁷ In the case of

Figs. 80.5A and B: (A) Sagittal and (B) axial computed tomography (CT) myelogram demonstrating adjacent segment stenosis at L4-L5 (arrows) above a previous decompression and fusion at L5-S1. Notice CT myelogram defines the presence of the interbody fusion (asterisk) and the extent of the bony decompression on the sagittal and axial images.

revision surgery, the use of MRI with gadolinium can help differentiate scar from recurrent disc material.

The disadvantage to MRI is high rate of false-positive degenerative changes. In an MRI study of 67 asymptomatic individuals, Boden et al.⁸ reported that in the patients aged 60 years or older, the findings were abnormal on about 57% of the scans; 36% of the subjects had a herniated nucleus pulposus, while 21% had spinal stenosis. There was degeneration or bulging of a disc at least one lumbar level in 35% of the subjects aged between 20 and 39 years and in all but one of the 60- to 80-year-old subjects.

A computed tomography (CT) myelogram is beneficial in patients who are unable to obtain an MRI due to medical or device-related issues such as cardiac pacemaker. A CT myelogram may also be considered to be the advanced imaging of choice in patients with spinal implants, where implant-related artifact can degrade the quality of the MRI images and identification of the trajectory, location, and position of the implants is required. A CT myelogram can also be beneficial in patients with significant spinal deformity and in revision cases where assessment of adjacent level disease or residual stenosis due to bony compression is suspected (Figs. 80.5A and B).

Because radiographic imaging demonstrating the presence of degenerative changes is very common in both MRI and CT myelogram, determination of the pain generator can be difficult. Due to this uncertainty, it is vital to correlate the information from clinical examination find-

ings, patient complaints, and imaging in order to prescribe the best treatment to patients with lumbar stenosis. Once the diagnosis of symptomatic spinal stenosis has been made, the advanced imaging is a preoperative to help assess the location and extent of stenosis.

INDICATIONS

Despite the fact that evidence supporting the nonoperative or conservative treatment for stenosis is scant, and a systematic review study by Ammendolia⁹ also failed to provide any moderate-to-high-quality evidence for the same, it is the authors' opinion that surgical management should be considered only after all other nonoperative alternatives have been maximized. Surgery for lumbar stenosis is indicated when there is a failure of conservative treatment and a significant effect on the patient's quality of life, and when other pathology has been ruled out. Lumbar epidural steroid injections, nonsteroidal anti-inflammatory drugs, physical therapy and activity modification are the mainstay of conservative treatments for lumbar stenosis and should be attempted first. The natural history of lumbar stenosis is a gradual onset of symptoms, and if there is rapid progression of symptoms, then other etiologies should be considered.

Decompressing the stenotic area is a proven and effective surgical treatment for lumbar stenosis. There are no absolute contraindications to surgery but a thorough history and physical examination should be undertaken with

careful attention to comorbidities that could cause perioperative complications. Once a clinical and radiographic diagnosis is confirmed, there are different surgical options and considerations for lumbar stenosis.

The principle of surgical treatment is to fully decompress the spinal canal in the areas of stenosis, whether it is the central, lateral recess or neuroforaminal zone. It is important when counseling patients with neurogenic claudication or radicular pain from lateral recess stenosis, that back pain due to disc degeneration or facetogenic pain may not be alleviated with decompression.

■ OPEN OPERATIVE TREATMENT USING LUMBAR STENOSIS: SURGICAL TECHNIQUES

General surgical considerations include obtaining a complete decompression while preserving motion segments. It is of utmost importance to preserve the stability of the spine when fusion is not planned. However, in the presence of deformity, segmental instability or iatrogenic instability, fusion with or without instrumentation should be considered.

Laminectomy with or without Foraminotomy

Open total laminectomy is a mainstay of treatment for lumbar central and lateral stenosis. For the standard midline posterior approach, the patient is positioned prone. A Jackson or Andrews table can be used as it allows the abdomen to hang free, which decreases intra-abdominal pressure and thus decreases epidural venous pressure and surgical site bleeding. Extension of the hips will recreate the physiologic stenosis allowing the surgeon to directly palpate appropriate decompression of the stenosis. The planned level can be established with an anteroposterior and lateral fluoroscopic view prior to incision. The incision should be centered around the planned levels of decompression based on pre-operative imaging. All radiographic areas of stenosis that correlate to the physical examination should be decompressed.

For a standard open posterior approach, the midline incision is carried down to the supraspinous ligament over the spinous processes. Electrocautery is used to subperiosteally dissect down onto the lamina. For a total laminectomy, the supraspinous ligament and spinous process can be removed. In order to preserve the supraspinous and interspinous ligaments above and below the planned

decompression levels, only one inferior half of these spinous processes are removed at these levels.

A curved curette can be used to detach the ligamentum flavum. Extreme care should be taken when dissecting down the lamina in order to avoid violation of the facet capsule. If necessary for complete decompression, up to 50% of the facet joint and lateral part of pars interarticularis can be removed for surgical decompression without causing any instability.¹⁰ Over resection of the pars can also lead to fracture and potential instability and should be avoided, if possible.

Hemilaminectomy with or without Foraminotomy

A fenestration or keyhole hemilaminectomy technique can be used for decompressions as well. In fact, in patients with unilateral single lateral recess stenosis without significant degree of central stenosis, a unilateral hemilaminectomy may be considered the procedure of choice. By definition, hemilaminectomies have the added benefit of preserving the midline ligamentous structures, more specifically the spinous process and the supra- and interspinous ligaments and, theoretically, have a lower risk for resulting segmental instability and adjacent segment disease. Furthermore, in some cases, bilateral hemilaminectomies or “box outs” can be used for patients with central stenosis.

In the hemilaminectomy, each planned level is sequentially decompressed by removing half of the inferior lamina for the cephalad vertebral body and the superior half of the caudad lamina on the symptomatic side. The ligamentum flavum attaches on the anterior aspect of the superior lamina and the superior aspect of the inferior lamina. Removing the superior hemilamina allows the release of the attachment site of the ligamentum flavum.

In the case of central stenosis, the central and contralateral stenosis can be addressed through either bilateral hemilaminectomies or through a unilateral approach by “airplaning” the operating table away from the operative side and decompressing the contralateral side while leaving the spinous process and interspinous ligaments intact. Although technically more demanding, this technique has been shown to be effective to achieve decompression without creating instability.

Foraminotomy

Foraminotomies are typically not preformed alone and are included as part of the laminectomy and hemilaminectomies.

Figs. 80.6A and B: (A) Preoperative lateral standing radiographs demonstrating the presence of spondylolisthesis in the presence of spinal stenosis. (B) Postoperative lateral standing radiographs demonstrating spinal fusion with posterior pedicle screw fixation and lumbar interbody fusion with postoperative reduction of the spondylolisthesis.

Direct foraminal decompression is performed by following the exiting root through the lateral recess out into the neuroforamen. This may require resecting the leading edge of the inferior lamina. The pars can be undercut utilizing the curved foraminotomy Kerrison Rongeurs that are designed to allow the surgeon to pass the Kerrison punch into the foramen and resect the ventral aspect of the pars, which makes up the posterior aspect of the neuroforamen. It is important during this maneuver to remain dorsal to the nerve root and care should be taken to avoid excessive pars resection.

Although controversial and beyond the scope of this chapter, indirect foraminal decompression through restoration of intervertebral disc height to address “up-down stenosis” has been advocated by some surgeons. Unfortunately, currently this can only be performed through interbody fusions either as an anterior lumbar interbody fusion, direct lateral interbody fusion, or posterior or transforaminal interbody fusion, depending on surgeon preference, location of pathology, and patient habitus and anatomy.

Spinal Fusion

Special consideration to fusion should be given in certain circumstances. If there is degenerative spondylolisthesis or scoliosis, signs of instability, or if the amount of decompression destabilizes the spine, then uninstrumented or instrumented fusion is recommended (Figs. 80.6A and B). On the preoperative MRI, facet cysts, fluid in the facets

(see Fig. 80.2B), and facet synovitis are signs suggestive of segmental instability.

Intraoperative assessment of the possible unstable level can be performed by gross assessment of the motion at the level. Preoperative flexion and extension films can document dynamic instability if greater than 3 mm of translation. Occasional on a revision or primary lumbar decompression, >50% of the facet or pars may need to be removed for adequate decompression. In such cases, fusion should be performed to prevent an iatrogenic instability.

A classic study by Herkowitz et al. demonstrated that inter laminar fusion in addition to decompression provided superior clinical results in patients with lumbar spinal stenosis and degenerative spondylolisthesis. The superior results of fusion in patients with spondylolisthesis as compared to stenosis have been confirmed in Spine Patient Outcomes Research Trial (SPORT) as well.¹¹ Instrumentation has also been shown to improve fusion rates. Instrumented fusion has thus been the treatment of choice when performing a fusion, although there is lack of evidence of a significant cost-effective benefit.

However, the inclusion of fusion with and without instrumentation in patients with stenosis without deformity and/or segmental instability is more controversial and unclear. Bae¹² analyzed the US nationwide data and reported that the trend of adding fusion to decompression procedure is increasing and that 26% of decompression surgeries in 2009 were combined with a fusion procedure for symptomatic stenosis without any evidence of slip.

Forsth¹³ reported the role of fusion in 5,390 symptomatic stenotic patients with a 2-year follow-up and concluded that the outcomes were similar for decompression as compared to decompression and fusion and that the addition of fusion to decompression was not associated with an improved outcome.

AUTHORS' PREFERENCES

It is the opinion of the authors of this chapter that whenever possible a decompression alone to address the area of symptomatic stenosis should be attempted. In case of preoperative evidence of instability, presence of deformity or an iatrogenic stability occurring due to the need for resection of supporting structures, fusion should be included. The inclusion of instrumentation is not required in all the fusion cases. However, in our experience, instrumentation improves the ability to restore a more physiologic coronal and sagittal alignment, while increasing fusion rates. Routine use of fusion procedures for patients with stenosis without any instability or deformity should be avoided.

OUTCOMES

There is good evidence to support that surgery for lumbar spinal stenosis is effective in relieving symptoms. Multiple studies have been performed; however, currently the SPORT study by Weinstein et al.¹⁴ provides level 1 evidence that surgery for the treatment of spinal stenosis is a viable and proven option when appropriate nonoperative care has failed. Furthermore, the results of the SPORT data at a follow-up of 4 years also demonstrate that the benefits and the quality-adjusted life year gained with surgery remains cost-effective.¹⁵

More specifically the SPORT study compared surgery versus conservative treatment in a multicenter study of patients having at least 12 weeks of symptoms and studied the outcomes at 6 weeks, 3, 6, 12, and 24 months. Of 289 surgically treated and 365 conservatively treated patients, patients who underwent surgery demonstrated significantly greater improvement in all primary outcomes than did patients who were treated nonsurgically at 2-year follow-up. The superior results of surgery were most pronounced at 3-month postoperative follow-up.¹⁴

When the study analyzed factors affecting the treatment outcome, Weinstein concluded that other than smoking, all analyzed subgroups that include at least 50 patients improved significantly more with surgery than with nonoperative treatment. This study showed that patients

with a baseline Oswestry Disability Index (ODI) ≤ 56 , patients who are nonsmokers, patients with the presence of neuroforaminal stenosis, patients with the predominance of leg pain, patients not lifting at work and patients with the presence of a neurologic deficit were all associated with greater therapeutic benefit with surgery as compared to the conservative treatment.¹⁶ Furthermore, the superior efficacy of surgery compared to nonoperative treatment was established at 4-year follow-up as well with regard to pain and function.¹⁵ In a cost-effective analysis as a part of SPORT, Tosteson¹⁷ studied 634 patients with spinal stenosis of which 394 (62%) underwent surgery and reported that the surgery is a cost-effective management tool as compared to other interventions for these patients.

COMPLICATIONS

Complications for open treatment of lumbar stenosis are not uncommon. Risk of mortality increases with age and the number of comorbidities. In general, the risk of mortality is $<1\%$, but in octogenarians there is mortality rate as high as 3% .^{10, 11}

Dural tear is a common complication of surgery for lumbar stenosis. Minimal invasive surgery has a slightly higher risk of incidental dural tears. This complication can lead to an increase in hospital stay, pulmonary and skin complications due to bed rest, and neurologic decline. There is a wide range of incidence in dural tears reported in the literature, from 1% to 17% . This complication is higher with decompression for lumbar stenosis, increasing age, and revisions. Persistent pseudomeningocele formation can lead to drainage, infection, and direct compression of neural elements. Adjacent level disease or reoccurrence of stenosis are some other complications associated with poor surgical outcome and patient dissatisfaction.

Kim¹⁸ analyzed the surgical outcome in 11,027 patients operated for stenosis without spondylolisthesis and reported the cumulative reoperation rate after surgery to be 4.7% at 3 months, 7.2% at 1 year, 9.4% at 2 years, 11.2% at 3 years, 12.5% at 4 years, and 14.2% at 5 years. The adjusted reoperation rate was not found to be different between decompression and fusion surgeries. The calculated reoperation rate was expected to be 22.9% at 10 years.

RECENT ADVANCES

A facet sparing decompression technique using the flexible microblade shaving system is reported to provide similar outcome as compared to the conventional

decompression techniques while sparing the facet to a greater extent with lesser blood loss and surgical time.¹⁹ Interspinous distraction techniques also offer outcome similar to decompression procedure with fewer complications related to the surgical procedure. However, the revision surgery rate is reported to be higher than the decompression or fusion surgeries.²⁰

CONCLUSION

Lumbar stenosis is becoming a more frequently recognized cause of neurogenic claudication and leg pain significantly affecting patient's quality of life. An attempt at nonoperative management is the first line of defense and there is good evidence that many patients can obtain significant relief. Once failing, conservative treatment decompression surgery has been shown to be a valid option to relieve symptoms and improve patient's quality of life. The surgery is not without risk of significant complications, and a thorough preoperative discussion is necessary in order to educate patients on the disease process and provide realistic expectations of the chosen treatment strategy.

INTRODUCTION

Reportedly, the first use of interspinous spacers dates back to the 1950s, when Dr Fred Knowles began placing metal “plugs” between the spinous processes of patients with spinal stenosis.¹ This practice did not persist due to frequent displacement of the implant requiring removal. Nonetheless, the use of interspinous process stabilization has recently seen a resurgence of both the number of available devices and their surgical indications.² Interspinous devices currently in clinical use in the United States and Europe include the Wallis device, DIAM, Coflex, Extensure H2, Aperius, and X-Stop. Proposed indications for these devices include treatment of lumbar spinal stenosis in patients with grade 1 degenerative spondylolisthesis, discogenic low back pain, recurrent lumbar disc herniation, and facet syndrome.³⁻⁷ Interspinous devices share a common goal of distraction between adjacent spinous processes, leading to decreased intersegmental motion, decreased foraminal and central stenosis, as well as alterations in load transfer across the motion segments in the lower lumbar spine. In this chapter, we will review the existing scientific literature concerning interspinous process spacer devices with regard to both biomechanical and clinical efficacy.

BIOMECHANICAL AND IMAGING STUDIES

Interspinous devices can broadly be divided into static and dynamic categories. Static spacers have been made

out of titanium, polyetheretherketone, and allograft bone. They are noncompressible and designed to maintain a minimum amount of distraction between the spinous processes of the diseased intervertebral level. The Wallis device utilizes synthetic straps to limit segmental motion in both flexion and extension while the Extensure H2 and X-Stop devices are fixed only to the superior spinous process allowing for flexion but providing a fixed block to extension. Dynamic devices are designed to similarly alter intersegmental motion while allowing for motion preservation. The Coflex device is composed of an axially compressible U-shaped piece of metal, while the DIAM device is composed of an elastomeric material.

Distraction of the interspinous processes is intended to cause local kyphosis at the instrumented intervertebral level. This can decrease invagination of the ligamentum flavum increasing canal diameter and also increase the size of the neural foramen. Richards et al.⁸ showed in a cadaveric model that placement of an X-Stop device significantly increased the canal area by 18% and the foraminal area by 25% by blocking extension at the instrumented level. Other investigators have confirmed these findings in vivo with up to 6-month follow-up by comparing magnetic resonance imaging (MRI) before and after X-Stop implantation.^{9,10} Consistent with the purported mechanism of interspinous spacer devices, the increases in canal and foraminal size were seen in the standing and extended positions, but not in flexed positions.

The Wallis device was initially used in patients undergoing surgery for recurrent disc herniation.² The underlying

rationale of this treatment is that distraction of the posterior elements can unload the disc that may have beneficial effects for both surgically and nonsurgically treated symptomatic disc degeneration. Although animal models have shown that sustained increased intradiscal pressures can induce disc degeneration,¹¹ intradiscal pressures of degenerated discs are usually significantly lower than those of healthy discs because of the inability of an incompetent annulus to maintain a loading environment.¹² Animal models suggest that intervertebral distraction may reverse some of the changes caused by compression-induced degeneration.¹¹ Interspinous spacers appear to be capable of reducing intradiscal pressure; one study demonstrated that implantation of an X-Stop device decreased intradiscal pressure by 43–63% with extension, 40–41% in neutral, and 17–38% in flexion.¹³ These effects are concentrated along the posterior annulus and disc that may be relevant in the setting of painful disc herniation.¹⁴ However, effects on restoration of disc height are minimal.¹⁵

A second potential benefit of altered loading across the intervertebral motion segment is unloading potentially painful and degenerated facet joints. Load across the facet joint is increased in extension and has been shown to be decreased by up to 55% following the implantation of an X-Stop device.^{16,17}

Motion sparing technologies have gained popularity due to concerns regarding the potentially deleterious effects of spinal fusion on adjacent motion segments. Multiple studies demonstrate that implantation of interspinous spacers including the X-Stop, DIAM, and Wallis devices decreases motion (flexion less than extension) at the instrumented level.^{3,14,18–21} However, there do not appear to be any changes in segmental range of motion at the adjacent levels. These studies also demonstrate that there is no alteration to the global alignment of the spine following instrumentation. A second described indication for stabilization using interspinous spacers is to restore stability to a segment that has undergone at least partial facetectomy as part of a surgical decompression. Several cadaveric studies have investigated the ability of interspinous spacer devices to restore segmental stability after increasing levels of resection of the facet joints.^{22–24} They appear to show a restoration of normal or near normal stability with levels of resection up to a unilateral complete facetectomy but not bilateral facetectomy. However, the clinical relevance of these findings is unclear.

CLINICAL RESULTS

The X-Stop device is the most extensively studied of the commercially available interspinous spacers, as this was the first such device to gain FDA approval and has served as the predicate device for this class of devices. X-Stop has been studied in two prospective randomized controlled trials. Zucherman et al. compared 100 patients treated with X-Stop to 91 controls managed nonoperatively.^{25,26} Inclusion criteria for the study were stringent. Patients should (1) be older than 50 years of age, (2) have leg, buttock or groin pain with or without axial back pain that is relieved by sitting, (3) be able to sit for minutes without pain, (4) be able to walk greater than 50 ft, (5) have completed greater than 6 months of nonoperative therapy, and (6) have radiographic evidence of spinal stenosis limited to one or two levels. Results at 1 year were analyzed using the Zurich Claudication Questionnaire (ZCQ) and SF-36. However, only the ZCQ was reported at 2 years. They observed clinically greater improvement at all time points compared to the controls with 60.2% of patients reporting improvement in Symptom Severity domain and 57% improvement in physical function at 2 years. A limited 4-year follow-up of 18 patients from the original surgical cohort demonstrated that 78% had a successful outcome assessed with Oswestry Disability Index (ODI).²⁷ Despite some methodologic limitations, this study does suggest that X-Stop is effective for the treatment of a selected group of patients with spinal stenosis.

Anderson et al. also studied the effect of X-Stop implantation in a prospective randomized controlled trial of 75 patients with spinal stenosis and grade 1 spondylolisthesis.²⁸ The reported clinical improvement of 63% of the surgical group versus 13% of nonsurgical controls using ZCQ and SF-36. Of particular note, the surgical procedure was not associated with progression of the patients' spondylolisthesis. However, a case series of 12 patients by Verhoof et al. reported a high rate (58%) of symptomatic progression of the spondylolisthesis requiring a second operation.²⁹ Other noncomparative studies demonstrate varying degrees of satisfactory outcomes.^{15,30,31}

Data regarding the clinical effectiveness of other interspinous spacers is limited and largely composed of studies that are noncomparative and/or retrospective. The developer of the DIAM implant, Jean Taylor, published a series of 104 patients in whom the device was implanted for a variety of lumbar disorders.³² He reported mixed results for improvement of pain and activities of daily living.

Two reports have investigated the effects of implanting DIAM devices following a lumbar decompression.^{33,34} Although, they report generally good results, they fail to demonstrate that any demonstrated improvement is due to the interspinous device beyond what would be expected from the decompression alone.

A notable indication of the Coflex device is implantation of the device at the superior adjacent segment to an instrumented segment at the time of the index surgery in order to “control” the increased motion at the adjacent level following surgery. Although this “topping-off” construct has been demonstrated to decrease the motion at the superior adjacent level, there were no clinical differences (ODI and VAS pain scores) between this construct and those patients who underwent instrumented spinal fusion alone.^{24,35} Coflex implantation after spinal decompression has also been studied in a prospective controlled study by Richter et al.^{36,37} Similar to the DIAM implant, they showed no difference in any clinical parameter between patients with the implant and those undergoing decompression alone with 2-year clinical follow-up.

Senegas has published his results with 13-year mean follow-up following implantation of the Wallis device following decompression for spinal stenosis or disc herniation.³⁸ Twenty of the 107 devices subsequently failed and required removal and segmental fusion. The remaining patients reported sustained benefit from the procedure based upon ODI, SF-36, and VAS pain scores. However, their claim that the use of the device saved patients from requiring spinal fusion is controversial both with respect to their indications for spinal fusion and the lack of a control group to demonstrate the clinical benefit was not due to decompression alone. The effect of the Wallis device has also been studied with respect to its ability to decrease the incidence of recurrent disc herniation following discectomy.³⁹ The authors found the rate of recurrent disc herniation following device implantation was no lower than the published figure in the literature of approximately 10%.

The Aperius device is another implant which has demonstrated good results in a noncomparative prospective study with 12-month follow-up.^{40–42} However, Postacchini et al.⁴³ prospectively compared a cohort of 36 patients with implantation of the Aperius device for spinal stenosis with similar controls undergoing traditional surgical decompression. At 2-year follow-up, only 31% of patients in the Aperius group with severe spinal stenosis had good outcomes assessed with ZCQ and ODI. Patients with moderate stenosis had better outcomes (60%) but there was a

17% failure rate. Aperius group results were uniformly worse than those for open decompression (80–89% good results).

COMPLICATIONS

Common complications following implantation of interspinous devices include spinous process fracture and device dislocation. Talwar et al. demonstrated that the force necessary to insert an X-Stop device in cadaveric spines ranged from 11 to 150 N.⁴⁴ The force necessary to fracture the spinous process was 95–786 N and was highly correlated with bone mineral density, suggesting that osteoporosis contributes strongly to fracture risk. The risk of fracture may also depend on the rigidity of the implant. The loads transferred from the Coflex device to the spinous process are 11.3% of the static load to failure, suggesting that fracture is less likely when using a more flexible implant.⁴⁵

Clinical failures have been reported for the X-Stop implant. Barbagallo et al. reported failure in 8 of the 69 patients (4 fractures, 4 dislocations, 11%) at 2-year follow-up, while Verhoof et al. reported a very high failure rate (58%) in patients with spondylolisthesis.^{29,46} Senegas had a failure rate of 18% using the Wallis device at a follow-up of 13 years.¹⁴ Aperius device failures have been reported at a rate of 17%.⁴³ There is very little data concerning the failure rates of other devices. The treatment of implant failure generally requires removal of the implant and decompression of the affected level.

COST-EFFECTIVENESS

The cost-effectiveness of interspinous devices has been compared to open decompression and conservative management in two studies with differing results. Skidmore et al.⁴⁷ utilized 2-year follow-up data from the X-Stop FDA trial to calculate cost-effectiveness data. They showed that the cost per quality adjusted life-years (QALY) of X-Stop versus conservative management for spinal stenosis was \$17,894. In comparison to open decompression, the X-Stop procedure was dominant in that it was both less expensive and provided better quality of life. This value falls well inside commonly accepted values of cost-effectiveness.⁴⁸ In contrast, Burnett et al.⁴⁹ also performed the same comparisons utilizing pooled data from a variety of sources. They concluded that the open decompression was the dominant treatment with a cost per QALY relative to conservative care of nearly \$60,000. As with all such studies, the conclusions are only as valid as the underlying data and assumptions. Skidmore et al. have criticized the study

by Burnett et al. citing: “(1) inclusion of papers from disparate patient populations, (2) use of untransformed SF-36 scores rather than utilities to inform QALYs, (3) inconsistent definitions of treatment failure, (4) lack of consideration about the frequency and costs associated with spinal fusion, and (5) outdated X-STOP payment mechanisms and amounts.” Clearly, further work is necessary to clarify this issue.

CONCLUSION

There are a wide variety of interspinous implants currently available for use in the United States and Europe. All share a common goal of interspinous process distraction leading to increased area of the spinal canal and neural foramen. Altered loading across the intervertebral motion segment may be beneficial, but these indications have not been clinically proven. The X-Stop device is the best studied with Level 1 evidence demonstrating its efficacy in the treatment of spinal stenosis and spinal stenosis with grade 1 spondylolisthesis.^{25,28} Data regarding the other devices is limited, but further clinical trials are underway. In the rare instances when interspinous devices have been compared directly to surgical decompression, the clinical results favor surgical decompression especially for patients with

severe spinal stenosis, but the cost-effectiveness data does not clearly favor one intervention over the other. We agree with the assessment of Sobottke et al. that patients suitable for implantation of interspinous process devices are relatively uncommon.⁵⁰ Only 17.5% of >1,000 patients in their series with intermittent neurogenic claudication met the criteria for implantation.

In our practice, we feel that interspinous process devices are beneficial for a very narrow group of carefully selected patients. Our indications include a clear story of intermittent neurogenic claudication with complete resolution of symptoms in the seated/flexed positions and evidence of mild-to-moderate spinal stenosis on MRI limited to one or two levels. We are more inclined to recommend an interspinous process device in those patients with disabling symptoms and concomitant multilevel pathology such as degenerative scoliosis or spondylolisthesis where a formal decompressive laminectomy might further destabilize the spine and require a spinal fusion (Figs. 81.1A and B). Some authors have also advocated the use of interspinous process devices in conjunction with discectomy for treatment of symptomatic disc herniation citing improvements in low back pain but this is not something we have incorporated into our practice.^{51,52}

Fig. 81.1A: A 67-year-old man with bilateral neurogenic claudication symptoms only with standing/walking. Preoperative anteroposterior radiographs demonstrate a degenerative scoliosis. Representative T2-weighted sagittal and axial magnetic resonance imaging demonstrate a segment with moderate stenosis.

Fig. 81.1B: Two-year follow-up radiographs after implantation of an X-Stop device at L3/4 and L4/5 demonstrate a stable degenerative scoliosis without development of any new instability. The patient continues to have an excellent symptomatic result.

INTRODUCTION

Degenerative spondylolisthesis (DS) is the translational displacement of one vertebral segment over an adjacent, inferior level as a consequence of degenerative changes, including aging and arthritis, that affect the integrity of the intervertebral disc and facet joints (Fig. 82.1).^{1,2} Degenerative spondylolisthesis was initially referred to as pseudo-spondylolisthesis by Junghanns due to the presence of an intact neural arch.^{2,3} The intact neural arch distinguishes DS from what, at the time, was thought to characterize spondylolisthesis: the presence of a defect in par inter-articularis or the isthmic region of the vertebral segment.² However, because all forms of spondylolisthesis involve a forward slippage of the cephalad vertebra in a spinal segment, Macnab referred to this condition as “spondylolisthesis with an intact neural arch.” Later, Newman coined the term “degenerative spondylolisthesis.”^{4,5} Unlike isthmic spondylolisthesis, DS is typically seen in middle-aged or older individuals and may be associated with symptoms from the presence of stenosis of the spinal canal and/or neural foramen.

ETIOLOGY AND DEMOGRAPHICS

Various factors have been suggested to play a role in the development of DS. Normal facet joints in the lum-

Fig. 82.1: Lateral X-ray of L4/L5 degenerative spondylolisthesis.

bar spine carry up to 33% of the axial load and between 3% and 35% of the compressive load, depending on the specific level and patient posture. As degeneration of the intervertebral disc ensues, the compressive loads on the facet joints can increase substantially, leading to facet joint degeneration and remodeling.⁶ Coronally oriented facet joints provide superior resistance to shear forces.⁷ The orientation of the facet joints can vary between individuals and between vertebral levels. In addition, with facet degeneration, it has been suggested that more

sagittally oriented facet joints may be produced.⁸ In addition, Blumenthal et al found that patients who had a facet angle of greater than 50° let to a 39% chance of slip progression in the setting of degenerative spondylolisthesis after a decompression alone.⁷⁰

A role for ligamentous laxity in DS has also been suggested. Most cases of DS occur at the L4–L5 or L3–L4 segments. The condition rarely affects the L5–S1 segment where ligamentous support is more robust despite the substantial shear forces present at the lumbosacral junction.⁹ Females are affected by DS much more commonly than males, which may be attributable in part to increased ligamentous laxity. Rosenberg et al. found DS to be four times more common in women and seldom observed the condition prior to the age of 50 years.⁹ Women not only develop DS more frequently than males, but also at a younger age.¹⁰ Imada et al. suggested a role for estrogen in the development of DS, demonstrating that oophorectomy was a positive risk factor for DS, despite similar facet orientation.¹⁰ Nadaud et al. did not find estrogen receptors in facet joint capsular ligaments in 14 samples of DS patients; therefore, the effect of estrogen may be indirect.¹¹

CLASSIFICATION SYSTEMS

Meyerding classified spondylolisthesis according to the degree of slippage: 0–25%, grade 1; 26–50%, grade 2; 51–75%, grade 3 and 76–100%, grade 4 (Fig. 82.2). Slippages greater than 100% are called either grade 5 or spondyloptosis.¹ The percentage of slip according to Meyerding is calculated as a/A , where a is the numerical measurement of how far the segment is displaced in an anterior direction, and A is the anteroposterior diameter of the segment on which the slippage has occurred.¹ Low-grade slips include grades 1 and 2. Pure DS almost exclusively involves low-grade slippage—most often grade 1 or 2.^{1,9}

Among cases of lumbar DS, there is significant heterogeneity in the radiographic characteristics of the slippage.¹² Surprisingly, no well-accepted classification system has yet been described for lumbar DS. Anderson et al. studied the radiographic characteristics of DS at the L4–L5 level to identify useful parameters in developing a clinically relevant classification system.¹² The data for angular and translational movement on neutral, flexion, and extension films were generally continuous in nature, suggesting a wide spectrum in the range of instability with this condition.¹²

Fig. 82.2: Meyerding classification system: lateral radiograph of a lumbar spine with spondylolisthesis at L4/L5 level.

Adding some radiographic parameters which is associated with DS, such as pelvic incidence, global alignment.

CLINICAL PRESENTATION/CHARACTERISTICS

Symptoms in DS patients can vary widely from asymptomatic, to back pain predominant symptoms, to those with severe symptoms of radiculopathy or neurogenic claudication. Collapsed disc space, ossified ligaments, sclerosis of cartilaginous endplate, and vertebral body spur formation are negative predictors for slip progression¹³; however, there is no specific correlation between the degree of slippage, slip progression and the onset or severity of symptoms in DS.^{13–17}

The symptoms most commonly requiring surgical management are those associated with spinal stenosis, including neurogenic claudication and radiculopathy caused by compression of neural elements at the site of the slippage.^{14,18–22} Leg pain symptoms in a unilateral or bilateral distribution are generally worse with standing and/or ambulation and better with forward flexion of the spine (e.g. with sitting or leaning on a shopping cart).¹⁸ Because symptom severity is not directly correlated with the degree of spinal canal narrowing, patient history plays the predominant role in clinical decision-making regarding the need for treatment in DS.²³

Radiculopathy from DS most commonly affects the L4–L5 segment and causes L5 radiculopathy, although symptoms of L4 nerve root compression may occur, if

significant stenosis exists in the L4–L5 foramen.^{19,24} Leg pain symptoms may follow either a classic dermatomal distribution or involve crampy pain in the buttock, thigh, and/or calf that progresses in a proximal to distal manner with standing and walking.²⁴

Nonoperative options for affected patients include activity modifications, nonsteroidal anti-inflammatory drugs, epidural injections, analgesic or nerve membrane stabilizer medications and exercise-based rehabilitation programs. Patients with severe or progressive symptoms despite nonsurgical care are generally considered candidates for surgery.

■ OPERATIVE INDICATIONS

Decision-making with DS, on the part of the clinician, is complex and involves careful consideration of the patient's symptoms, disability caused by the disease, response to treatment and medical history. Unfortunately, nonoperative treatments usually do not produce long-term relief for those with severe, long-standing or recurrent leg pain in the setting of DS.^{14,22,25,26} The Spine Patient Outcomes Research Trial (SPORT) was a study designed to follow both a randomized and an observational cohort with DS subsequent to operative or nonoperative treatment for DS. Weinstein et al. reported that operative treatment resulted in superior patient outcomes in terms of decreased pain and functional recovery using patient-based outcome measures.²⁷

■ OPERATIVE APPROACHES

Simple Decompression

Surgical decompression addresses the issue of stenosis-induced symptoms for patients with DS, but it does not address the potential instability of the spinal segment.²⁸ Traditionally, decompression has involved a lumbar laminectomy. Some have suggested that a wide laminectomy is necessary to reduce the risk of bone regrowth and resulting recurrent stenosis.²⁹ Unfortunately, wide lumbar decompression is associated with a risk of progressive spinal instability that can lead to a recurrence of symptoms and poor clinical outcome.²⁹

Several authors have reported that simple decompression can be an effective means of treating DS.^{14,30} Dall and Rowe suggested that patients subjectively improve more with laminectomies and partial facetectomies compared to laminotomies or foraminotomies, and thus advocated a

more extensive decompression.¹⁶

Several studies have found that patients are prone to postoperative slip progression following wide laminectomy.^{14,15} This may be due to the loss of stability associated with the removal of posterior ligamentous structures (supraspinous, interspinous ligaments, and ligamentum flavum) and the resection of portions of the facet joint as part of the decompression.³¹ Some have reported that more extensive decompressions, involving a greater number of levels, present a higher risk for postoperative instability.^{20,32} However, in Rosenberg's experience, postoperative slippage often ceases following the first year.²⁰ Unfortunately, instability of the segment may be a source of additional symptoms, requiring revision surgery.¹⁴ For this reason, patients should be informed regarding the possible need for additional surgical intervention if a decompression alone is done in the setting of DS.³⁰

Proponents of decompression alone for DS argue that the increase in the cost of doing a fusion may not be warranted in all cases.^{33,34} Kim et al. suggested that patients with stable spondylolisthesis and leg-dominant pain could be adequately treated by simple decompression, without fusion, based on the substantial increased costs of a fusion with only minor gains in clinical outcome.³³

With the advent of less invasive or minimally invasive decompression techniques, there has been the resurgence in interest for decompression alone as a treatment strategy for DS with leg-dominant symptoms.³⁴ Kelleher et al. demonstrated that decompression alone using a minimally invasive technique could produce favorable clinical results with substantially less morbidity compared to lumbar fusion.³⁴

Decompression and Uninstrumented Fusion

The use of fusion to supplement decompression in the setting of DS has been debated.³⁵ Unfortunately, it is not always easy to compare various clinical series in the literature due to differences in patient demographics, surgical technique and methods of measuring clinical outcome.^{35,36}

Martin et al., in a retrospective cohort study, demonstrated a decreased likelihood of reoperation following a decompression and fusion compared to simple decompression alone.³⁷ Herkowitz and Kurz published a landmark prospective, randomized study involving 50 patients with DS treated by either simple decompression or decompression with an uninstrumented fusion.³⁵ In this study,

they found that posterolateral fusion yielded superior outcomes compared to decompression alone. Surprisingly, the clinical outcomes in the fusion group were more favorable irrespective of whether patients achieved a successful radiographic fusion.³⁵ The use of fusion combined with decompression has been routine in the practice of many surgeons when treating DS, based in large part on Herkowitz and Kurz's study.³⁵ In the SPORT study, 95% of surgical subjects enrolled underwent fusion, despite the absence of a requirement to use fusion for this diagnosis in the study protocol.²⁷

Postacchini and Cinotti studied the long-term outcomes of patients treated surgically for spinal stenosis.²⁹ They found some degree of bone regrowth in all patients regardless of whether or not a fusion had been performed. The magnitude of bone regrowth was significantly less, however, in those treated with a fusion.²⁹ Patients with more bone regrowth had worse clinical results, compared to those with less bone regrowth.

While decompression and fusion, without instrumentation, is more costly compared to decompression alone, it is still substantially less costly compared to an instrumented fusion.³⁸

Decompression and Instrumented Fusion

The use of spinal instrumentation, usually involving pedicle screw fixation (Figs. 82.3A and B), to supplement spinal fusion has also been debated.³⁸ Despite this, supplemental instrumentation for those patients with DS undergoing

decompression and fusion has become commonplace in the United States due to the touted advantage of an increased fusion rate.^{33,34,39} Unfortunately, improvement in long-term clinical outcome with the use of spinal instrumentation has yet to be proven conclusively. One reason for the difficulty in interpreting the clinical data available in the literature on this topic is an overreliance on radiographic results instead of a focus on patient-based clinical outcomes.²⁵ Only in recent years have patient-based outcome measure begun to become commonplace in clinical studies.

Fischgrund et al. performed a prospective, randomized study comparing the effects of decompressive laminectomy and fusion with and without supplemental instrumentation.³⁹ They found a significantly higher fusion rate when pedicle screw fixation was used (82% compared to 45% without). Despite this, no significant improvement in clinical outcome was found for the patient cohort treated with pedicle screw instrumentation. In this study, radiographic fusion did not correlate strongly with clinical outcome and patients with a "fibrous union" achieved a favorable clinical outcome in some instances. In a longer-term follow-up study of the same patient population, Kornblum et al. found less back and lower leg pain in patients who had achieved successful arthrodesis (86% vs. 56% good/excellent), suggesting a potential clinical benefit for spinal instrumentation at least in the long run.²⁶

Bridwell et al. performed a prospective, randomized study of 49 patients with an average follow-up of 3 years.⁴⁰ In this study, they included three treatment groups: Group 1, no fusion; Group 2, decompression and fusion; and

Figs. 82.3A and B: Anteroposterior and lateral radiograph following posterolateral fusion and pedicle screw fixation.

Table 82.1: Comparison of the pros and cons of simple decompression, decompression with fusion, and decompression with instrumented fusion.

	<i>Pros</i>	<i>Cons</i>
Decompression	<ul style="list-style-type: none"> • Addresses the issue of stenosis • Cost-effective compared to fusions • May be the optimal choice for certain types of degenerative spondylolisthesis 	<ul style="list-style-type: none"> • Does not address the issue of instability • Risk of bone regrowth • Postoperative slip progression • Instability may require revision surgery
Decompression and uninstrumented fusion	<ul style="list-style-type: none"> • Addresses issue of stenosis and instability • Superior clinical outcomes to simple decompression whether fusion is achieved or not • Lower amount of bone regrowth post-decompression 	<ul style="list-style-type: none"> • Higher costs compared to simple decompression • Decreased fusion rate when compared to instrumented fusion
Decompression and instrumented fusion	<ul style="list-style-type: none"> • Benefits of uninstrumented fusion with the added benefit of higher fusion rates • May be superior to uninstrumented fusion because of some evidence associating pseudoarthrosis with decreased clinical outcomes 	<ul style="list-style-type: none"> • Significantly more expensive when compared to simple decompression or decompression and uninstrumented fusion • Short-term clinical benefits are not superior to those of uninstrumented fusion

Group 3, decompression and fusion with pedicle screw fixation.²⁶ As with the Fischgrund study, Bridwell et al. found a significant increase in fusion rate with instrumentation (87% compared to 30%). Walking capacity, the only functional measure collected in the study, improved more in the patients who achieved a successful fusion. In addition, less slip progression was noted in the instrumented group compared to the other groups.

Yuan et al. performed a large, historical cohort study with 2,684 subjects with DS.⁴¹ They found that patients with pedicle screw fixation achieved a higher fusion rate compared to those who underwent uninstrumented fusion. The fused patients also enjoyed better functional outcomes and superior regression of neurological symptoms.⁴¹ Despite the risk of implant breakage and loosening, the authors concluded that the use of pedicle screw fixation outweighed the drawbacks.⁴¹

In contrast, Thomsen et al. studied the use of pedicle screws for lumbar fusion and found that the complications associated with pedicle screw fixation were high, potentially outweighing the benefits.⁴² In their prospective, randomized trial involving 130 subjects, patients were randomized to fusions with or without pedicle screw instrumentation. The authors reported increased blood loss, operative time, risk of nerve injury, and revision rates in the group receiving instrumentation.⁴² It should be noted, however, that this older study may not be representative of current complication rates, as most technical complications have been shown to be reduced with increased surgeon experience.⁴³⁻⁴⁵

Ultimately, each of the aforementioned surgical approaches is coupled to pros and cons that a surgeon must take into consideration on a case-to-case basis when treating DS (Table. 82.1). Because of this, an open discussion of the options, risks and benefits for the treatment of DS should be conducted with the patient, leading to the opportunity for shared decision-making.

Forsth et al. recently published a randomized control trial of fusion vs decompression for lumbar stenosis in 247 patients (Swedish Spinal Stenosis Study). Of those patients, 135 patients had both stable and unstable degenerative spondylolisthesis. Degenerative spondylolisthesis in that study was defined as greater than a 3 mm slip without flexion extension views taken; the average preoperative slip was 7.4 mm. Two and five year follow up found that there were no differences in visual analogue pain scores, Oswestry Disability Index, and all other patient reported outcome measures between the two groups. However, it should be noted that 20% of the decompression patients had it performed minimally invasively. The re operation rate at 6.5 years was 22% in the fusion group and 21% in the decompression group.⁷¹ Ghogawala et al. published a randomized control trial in North America of 66 patients of fusion vs decompression for degenerative spondylolisthesis (SLIP-Spinal laminectomy vs Instrumented pedicle screw trial). All of the patients had a Grade 1 stable spondylolisthesis and excluded patients who had a >3 mm translation on flexion extension views. The average preoperative slip was 6 mm with 1.5 mm of translation. At 1, 2, and 4-year follow-up, fusion was better than decompression for the PCS (physical component score of the SF-36) at all time

points though there were no differences in the Oswestry Disability Index. The reoperation rate was 34% in the decompression group vs 14% in the fusion group.⁷² The conclusions of both studies do not clearly differentiate between “stable” vs “unstable” slips. There are obvious differences between patients who have a collapsed disc with fixed slips vs those with a large disc, bulky fluid filled facets, and >4 mm of dynamic instability. Despite slip progression, a “stable” degenerative spondylolisthesis may be adequately treated with a decompression alone. However, the ideal treatment of an “unstable” degenerative spondylolisthesis remains unknown. Revision surgery was at the discretion of the surgeon which may skew rates of revision surgery in both the Forsth and Ghogawala study.

Interbody Fusion

The rationale for interbody fusion involves the potential benefits associated with increasing anterior column support, increasing the area for fusion and re-establishing interbody height.⁴⁶ The drawback of interbody fusion involves the increased surgical complexity and cost of an interbody fusion procedure. The risks and benefits must be weighed in light of the patient’s particular situation when deciding on a surgical approach.

Posterior Lumbar and Transforaminal Lumbar Interbody Fusion

Using either a posterior lumbar interbody fusion (PLIF) or transforaminal lumbar interbody fusion (TLIF) approach, surgeons are able to reconstruct the disc space during the surgical procedure for DS.^{47,48} It is important for the surgeon to be experienced with the specific technique chosen as the risks and complexity of an interbody fusion are generally greater compared to posterolateral fusion.^{46,49} Although surgeon preference plays a role in surgical decision-making, the cost, operative time and patient morbidity must be considered as a part of the decision.

The more popular approach currently is the TLIF, which was described by Harms and Jerszenszky as a modification to the PLIF procedure.^{46,48} Transforaminal lumbar interbody fusion is felt by many to be the simpler and safer operation due to the reduced need for dural retraction and the simplified reconstruction of the disc space. When comparing TLIF and PLIF, Humphreys et al. showed that PLIF patients had greater blood loss, length of hospital stay, and operative time, while the TLIF patients sustained fewer

complications.⁵⁰ However, modern PLIF surgeons have generally modified the older PLIF approach to include wide removal of the facet joints, making the modern PLIF approach safer compared to the older PLIF technique and more similar to a bilateral TLIF.

Patients with DS may, in some cases, present challenges with a PLIF or TLIF procedure. Patients with significant stenosis will require substantial removal of the facet to provide safe access to the lateral disc space. In addition, patients with severe disc space collapse may have minimal room caudal to the exiting nerve root, thus limiting access to the disc space. Also, older patients with significant osteoporosis may not have adequate bone quality in the endplate region to support interbody devices and can have a high rate of inadvertent endplate violation during disc space preparation. Despite these challenges, PLIF and TLIF are useful adjuvants to the surgical care of selected patients with DS.

Anterior Lumbar Interbody Fusion

Anterior lumbar interbody fusion (ALIF) provides excellent access for disc space preparation and grafting. However, this approach presents the risk of injury to major vital structures and may require the assistance of an exposure surgeon. In addition, the ALIF procedure fails to provide access to decompress the subarticular region where there is often facet hypertrophy causing neural compression. Thus, ALIF may need to be combined with posterior column decompression and fusion to provide both stabilization and subarticular decompression. For these reasons, ALIF is less commonly performed compared to posterior-only approaches for DS. Despite this, there are patients where ALIF may be a reasonable consideration. Satomi et al. recommended the use of ALIF for early stage DS when the nerve compression symptoms were related more to instability as opposed to structural facet hypertrophy.⁵¹ Another situation where ALIF may be considered is when stenosis predominantly affects the foraminal zone with less significant lateral recess or central narrowing. Interbody distraction is capable of achieving “indirect” decompression of the foraminal zone in many such cases, without the need for a laminectomy. Inoue et al. also found ALIF to be a reliable solution for selected cases of DS, particularly those with significant segmental instability who were younger than 60 years of age.⁵² The later stages of DS have generally been found to require additional

decompression of the posterior column to achieve adequate decompression.⁵¹

Minimally Invasive Procedures

Minimally invasive procedures are attractive from the standpoint that they potentially offer a way to reduce perioperative morbidity, recovery time, and pain.⁵³ Unfortunately, strong evidence favoring minimally invasive surgery over traditional surgery for DS is currently lacking in the literature.⁵³ In addition, the steep learning curve associated with minimally invasive approaches prevents many surgeons from considering this option.⁵³

Rampersaud et al., in an observational cohort study, demonstrated a significant decrease in the length of hospitalization and blood loss along with a decreased need for a blood transfusion for patients treated with a minimally invasive surgical approach.⁵³ They also found reduced costs with minimally invasive surgery, due in large part to reduced hospitalization.⁵³

Wang et al. studied 85 patients following either traditional, open TLIF or a minimally invasive TLIF.⁴⁸ In this study, the operative times and postoperative radiographic results were similar for both groups; however, the minimally invasive group demonstrated a significantly shorter hospital stay, less blood loss, less need for transfusion and decreased back pain.⁴⁸ One drawback of the minimally invasive approach was the substantial increase in the use of fluoroscopy.⁴⁸ Price et al found that minimally in-

vasive TLIF produces comparable clinical and radiologic outcomes (90% fusion rates in both groups) to open TLIF with the benefits of decreased intraoperative blood losses, shorter operative times, shorter hospital stays, and fewer deep wound infections.⁷³

Lateral interbody fusion (XLIF or DLIF) is another less-invasive fusion technique that has gained popularity in recent years (Fig. 82.4). This approach provides access to the lumbar spine above the L5-S1 level utilizing the retroperitoneal space and transpsoas approach.⁵⁴ This approach has been recently assessed by Marchi et al. who suggested that the lateral approach was beneficial in patients with low-grade DS.⁵⁵ Although the approach has certain advantages including reduced soft tissue morbidity, preservation of the anterior and posterior longitudinal ligaments, and good interbody distraction, there are also drawbacks to consider including increased cost, the possible need for additional posterior column surgery and the risk to adjacent structures in the region of the operative field. As with other interbody approaches, the XLIF/DLIF approach may be useful in selected cases of DS. Patients who are candidates for lateral fusion without direct decompression have stenosis secondary to dynamic compression (i.e. patients who have pain with walking/standing that reduces with sitting or laying flat in the setting of >4 mm of instability of 10° kyphosis). Radiographic analysis should show reduction of the spondylolisthesis on a supine (CT, X-ray, or MRI) when compared to an extreme flexion X-ray. Candidates who have lateral

Fig. 82.4: Anteroposterior and lateral X-ray following direct lateral interbody fusion and percutaneous pedicle screw fixation.

recess and foraminal stenosis are better candidates for indirect decompression than those with central stenosis.

Nonfusion Strategies

Presently, decompression with fusion is the most common surgical approach used for lumbar degenerative instabilities.⁵⁶ However, concern over the effects of fusion on adjacent vertebral segments has led some to consider alternatives to lumbar fusion for the DS population. A variety of medical devices have been studied in small patient cohorts to provide stabilization without arthrodesis. Unfortunately, most of these devices have not yet been subjected to rigorous clinical studies and therefore strong evidence for the efficacy of these devices is currently lacking in the DS population.⁵⁷ Broadly speaking, the devices can be divided

into interspinous devices, pedicle-based devices and facet replacement devices.

Examples of the interspinous devices would include the X-STOP (Fig. 82.5) and Coflex (Fig. 82.6).⁵⁶⁻⁵⁸ Different interspinous devices restrict spinal motion in various directions depending on the design of the specific device. Some studies have suggested that interspinous devices were capable of achieving superior clinical results compared to nonoperative treatment or even fusion.^{57,59,60} The overall complication rate with initial implantation of interspinous devices has generally been low.^{59,60} Unfortunately, symptomatic relief may not last and revision surgery may be required in a substantial proportion of patients with instability and stenosis treated with an interspinous device.⁶¹

Fig. 82.5: Lateral and posterior view of implanted X-STOP device.

Fig. 82.6: Lateral and sagittal views of implanted Coflex device.

COSTS

Costs associated with spinal interventions have fallen under increased scrutiny in recent years. Between 1997 and 2005, the aggregate total costs of spine care rose by 65%.⁶² However, during this time, patient care and outcomes failed to demonstrate a corresponding increase.⁶⁷ Economic realities have led to the push for a value-based healthcare system. Such a system would take into consideration the cost-effectiveness of an intervention based on its estimated value—defined as quality over total costs. Attempts to measure the parameters of quality and costs have unfortunately been complicated and slowed the movement toward such a value-based system. Currently, there is debate over which factors appropriately qualify for the measurement of quality and costs. Although there is no lack of costs analyses for spine care in the literature, the available studies generally have limitations and the field of cost analysis requires additional standardization in methodology before it will be possible to smoothly compare the value of various approaches to spinal problems.

Most often, the cost-effectiveness of an intervention is measured as costs per quality adjusted life year (QALY). In the United States, the traditional threshold for a cost-effective intervention is one that costs less than \$100,000 per QALY.⁶³ Using the 2004 Medicare payment rate, Tosteson et al. calculated the costs per QALY for the surgical treatment of DS over nonoperative care at \$115,600 although this cost would be expected to reduce if the treatment effect gained through surgery showed longer durability.⁶¹

Longer-term studies will be required to define better the true cost-effectiveness of surgery for DS.⁶⁴

COMPLICATIONS

Potential complications are inherent to all surgical interventions. However, with knowledge, experience and meticulous technique, complications can be minimized.⁴⁹

In addition to the general surgical complications, treatment of DS by lumbar decompression without fusion risks complications such as iatrogenic facet, pars fracture or future instability. In addition, there is a risk of bony regrowth and restenosis, requiring additional surgery.^{14,15,29} As with all decompressions, postoperative hematoma can lead to neurologic deficits.⁶⁵

With larger and more complex surgeries, the risk of complications increases. Deyo et al. found that subjects undergoing fusion, compared to those with simple decompressions, had a 5.8 times greater rate of blood transfusion, a 2.2 times greater nursing home placement rate, a 1.5 times higher rate in hospital charges, and a 1.9 times greater complication rate.⁶⁶ Pseudarthrosis and instrumentation failure are potential complications of fusion procedures.^{26,41} Smoking and diabetes have been shown to decrease the rate of successful fusion.⁶⁷ Following fusion, motion of adjacent levels may be increased and this theoretically may lead to the risk of adjacent segment degeneration, requiring additional surgery.⁵⁷ The risk for this may be higher in postmenopausal women.^{57,68} Neurologic complications, while rare, may occur with any spinal

procedure. Hosono et al. found that prolonged operative time was a risk factor for neurological complications, due to prolonged retraction of the dura or nerve roots.⁶⁹

KEY POINTS

- Degenerative spondylolisthesis is the translational displacement of a vertebral segment over an adjacent, inferior level as a consequence of degenerative changes including aging and arthritis that affect the integrity of the intervertebral disc and facet joints.
- Patients with DS can vary widely from asymptomatic, to those with back pain predominant symptoms, to those with severe symptoms of radiculopathy or neurogenic claudication from spinal stenosis.
- For most patients, nonoperative or conservative treatments provide at least some temporary symptom relief; however, in patients with severe symptoms who fail to respond to nonsurgical care, operative intervention is generally more successful in reducing symptoms.
- Currently, the most common surgical approach for patients with DS involves performing a decompression and fusion procedure.
- The benefits of supplemental pedicle screw instrumentation continue to be debated, although instrumentation has been associated with a higher rate of radiographic fusion success.
- Recently, there has been interest in the spinal community regarding the use of minimally invasive and nonfusion devices for the DS population. The current literature is still inconclusive on the role of these developing treatment strategies.

INTRODUCTION

High-grade lumbar spondylolisthesis, which is of grade 3 or more by the Meyerding classification, or has a percent slip of 50 or more, is rare compared to the low-grade spondylolisthesis.^{1,2} There are two types of high-grade lumbar spondylolisthesis: (1) the L5 simply slips anteriorly with respect to S1 (low-grade dysplastic type by the Marchetti classification)³ and (2) the L5 vertebral body slips anteriorly and rotates around S1's superior end plate, i.e. the defect involves both the vertebral slip and kyphosis at the lumbosacral junction as a result of vertical sacral slope (high-grade dysplastic type).³ Posterior reduction is typically indicated for the low-grade dysplastic type, whereas the high-grade dysplastic type often requires lumbosacral kyphosis correction in addition to slip reduction.

Spondylolisthesis occurs and progresses most frequently during the growth period. In contrast, slip progression is rare after skeletal maturity. Biomechanical studies suggest that the slip occurs between the growth plate and the osseous end plate, which is biomechanically weak.^{4,5} The pathomechanism of the rounding deformity of the sacrum involves deficient endochondral ossification of the growth plate in the superoanterior corner of the S1 vertebra.^{6,7}

CLINICAL SYMPTOMS

According to Boxall et al.,⁸ only a few patients (4.7%) with high-grade spondylolisthesis are asymptomatic. Low back

or buttock pain is the most frequent complaint (79%). The exact mechanism of low back pain is still unclear. However, segmental instability or pars defect is likely to impact the onset of clinical symptoms. Heart-shaped or flattened buttocks are often seen in patients with high-grade spondylolisthesis. Tight hamstrings (65%)⁸ may contribute to sagittal imbalance and difficulty walking. The typical gait pattern is described as a "pelvic waddle" in which patients walk with their knees slightly flexed. The hyperlordotic lumbar spine and hips are stiff, and there is a tendency to walk on toes⁹ (Fig. 83.1). Uni- or bilateral radiculopathy to the thigh, leg, or foot is also frequently seen (62%).⁸ The step-off or displacement of spinous processes may be noted. During preoperative evaluation, patients should be carefully examined for motor and sensory deficits of the lower extremities. Rare bladder dysfunction can also occur in patients with high-grade spondylolisthesis.¹⁰⁻¹² Therefore, bowel and bladder function should be carefully assessed as well.

Regional and global spine alignment and flexibility should be checked before surgery.

TREATMENT

The natural history of high-grade spondylolisthesis has received little attention in the literature. Although low-grade spondylolisthesis has been shown to cause symptomatic

Fig. 83.1: Standing posture of a patient with high-grade spondylolisthesis.

progression in only a small percentage of subjects in long-term follow-up studies,^{2,13} the majority of high-grade spondylolisthesis patients develop significant symptoms at an early age. Therefore, many surgeons recommend surgery for high-grade spondylolisthesis.¹⁴⁻¹⁶ After skeletal maturity, significant progression of the slippage can occur, accompanied by worsening symptoms and limitations in activity, even though the patient may have been asymptomatic in their childhood or adolescence.⁸

There are many different surgical options to treat high-grade spondylolithesis.^{10,17-25,29} Decompression alone without fusion results in increased postoperative slippage. Therefore, the consensus is to perform spinal fusion. However, surgical approach, fusion levels, and slip reduction remain controversial.

Spinal Deformity Study Group (SDSG) has advocated a new classification for spondylolisthesis. Some sagittal alignment concepts should be included in this chapter for strategies of surgery according to this classification may be varied.⁴⁰

In Situ Spinal Fusion

In situ posterior spinal fusion, which has the advantage of less neurologic injury, has been recommended in some reports.²⁶⁻²⁸ Direct comparison of in situ fusion and fusion with reduction suggests that functional and clinical outcomes are equivalent, with a lower risk of neurologic injury for patients not undergoing reduction.^{27,28} However, major problems associated with in situ fusion are as follows:

(1) a high prevalence of pseudarthrosis, (2) progression of spondylolisthesis after surgery, (3) cauda equina syndrome despite successful solid bony fusion, (4) residual cosmetic deformity, (5) lumbosacral deformity resulting in sagittal imbalance, and (6) a small possibility of iatrogenic nerve root injury.

FUSION WITH REDUCTION

Some recent reports have recommended posterior correction and fusion using instrumentation, and this technique has gained popularity because of the ability to attain rigid fusion with good postoperative sagittal balance.^{24,25,30} Lamartina et al.²⁹ emphasized the restoration of sagittal balance being more important than reducing the vertebral slip. They reviewed the published cases of patients who underwent substantial reduction for high-grade spondylolisthesis. A total of 12.5% of patients experienced neurological deficits postoperatively, but most (71.4%) were transient.

In high-grade spondylolisthesis, a congenital sacral anomaly or secondary deformity contributes to the mechanical instability at the lumbosacral junction. Anterior reconstruction with a fibular strut graft or interbody cage is necessary because anatomic factors, such as trapezoidal L5 vertebral body or rounded sacral dome, may contribute to failure of fusion. Petraco and colleagues showed in a cadaver study that 71% of the total L5 nerve strain occurs during the second half of reduction.³¹ Thus, they recommended partial reduction because it is safer than complete reduction. Furthermore, they revealed that the correction of lumbosacral kyphosis in high-grade spondylolisthesis relaxes the L5 nerve root and may be neuroprotective. Restoration of the slip angle with partial reduction has been also recommended in other reports.^{17,30-34} We recommend that the slip be reduced to under 25% to obtain enough space for interbody fusion and that the slip angle be restored as much as possible.

Grade V spondylolisthesis, or spondyloptosis, is rare and carries a higher risk of nerve injury. In patients with spondyloptosis, the L5 body is completely translated anteriorly and/or inferiorly slipped below the sacrum. Surgical treatment for this unusual deformity can be challenging. Fusion without reduction using a fibular strut graft, as described by Smith and Bohlman, has a lower risk of iatrogenic nerve root injury when compared to fusion with reduction.³⁵ Gaines and Nichols described a two-stage operation, involving complete removal of the L5 body

anteriorly, followed by posterior reduction of the spondylolisthesis.¹⁸ Although spinal realignment and neurologic improvement were achieved, 77% of patients had some temporary L5 root deficit at long-term follow-up.³⁶ Recently, Kalra et al.¹⁰ introduced a modified Gaines procedure, which is similar to the original method except that they resected only the lower half of L5 anteriorly to avoid excessive shorting of the thecal sac. Resection of the sacral dome which is a shortening osteotomy of the spine allows a single-stage reduction of L5 without lengthening of the lumbosacral region is another choice in patients who have high grade spondylolisthesis.⁴¹

SURGICAL TECHNIQUES

Optimal fusion levels, L4 to S1 versus L5 to S1, for severe spondylolisthesis remain controversial. Kyphosis correction using L4 pedicle screws has been advocated by some authors.^{24,37,38} In our experience,³⁹ there was no significant difference in the correction rate between an L5 to S1 fusion group and an L4 to S1 group. However, operation time was shorter and there was less estimated blood loss in the L5-S1 group. Therefore, we now perform one-stage posterior correction at L5-S1 and save the L4-L5 motion segment. Although some authors recommend a plate system, we prefer a rod-and-pedicle screw construct because it is easy to apply distraction and compression forces. Our surgical techniques are as follows:

1. The patient is positioned prone with maximum hip extension on a radiolucent Hall frame (Fig. 83.2). Positioning is very important to reduce the deformity and to create lumbar lordosis. If the L5-S1 segment is mobile, this corrects the slip angle and pelvic retroversion. The patient's knees should be flexed on a cushion to reduce nerve root tension. At this point, neuromonitoring is performed to determine the baseline status, especially for the *tibialis anterior* and *extensor hallucis longus*, which are often innervated by the L5 nerve root. If the patient complains of radicular pain or motor weakness, the laterality on both sides is carefully checked.
2. An image intensifier is positioned to obtain an accurate lateral view of the lumbar spine. Insertion of L5 pedicle screws is difficult because the L5 vertebra is deep anteriorly.
3. Using the midline posterior approach, the L5 to S2 segments are widely exposed. The presence of spina bifida occulta is carefully determined on preoperative

Fig. 83.2: The patient is positioned prone, with maximum hip extension.

radiographs. If the patient has spina bifida occulta, subosteal exposure around the midline of the sacrum is carefully performed to avoid an incidental durotomy. Exposure lateral to the transverse processes is usually difficult due to the anterior L5 vertebral body slippage. Although it is difficult to expose the whole transverse process, proceeding ventrally along the interarticular process helps to identify it.

4. First, complete L5 laminectomy is performed. If there is spondylolysis, Gill laminectomy is performed. Fibrocartilaginous tissue and ragged bone from the area of the lysis edge are removed with Kerrison rongeurs and curettes. Some of the fibrocartilaginous tissue may extend into the foramen, and this should be removed completely. Next, partial S1 laminectomy is performed. The L5 nerve root should be exposed as far laterally as possible to ensure adequate visualization (Fig. 83.3). Occasionally, the L5 nerve roots are difficult to identify because of severe slippage. The foramen is decompressed along the L5 nerve root tract.
5. To obtain sufficient correction, pedicle screws need to be precisely inserted. Fluoroscopic guidance is, therefore, used to place all the pedicle screws. In particular, the S1 pedicle screws are placed cephalad from a slightly caudal starting point, which allow us to obtain a long lever arm during reduction (Fig. 83.4). Accurate insertion into the promontorium leads to tricortical purchase. Although some authors recommend a plate system, we prefer a rod system, which permits the application of distraction and compression forces.

Fig. 83.3: The L5 and S1 wide laminectomy is performed to observe the nerve root during reduction.

Fig. 83.4: Pedicle screw insertion is guided by fluoroscopy.

Fig. 83.5: Both lordosis rods are placed before reduction.

Fig. 83.6: Nuts are installed gradually on L5 pedicle screws with distraction forces.

6. The L5-S1 intervertebral disc is incised with a knife and removed with an intervertebral disc shaver. The disc space is usually narrow. The purpose of disc resection is to release the anterior elements at this point. Wide resection of the intervertebral disc should be performed to avoid L5 impingement by posterior disc bulging during reduction.
7. A rod with sufficient lordosis is applied to the pedicle screws (Fig. 83.5). Nuts are installed and tightened on the S1 pedicle screws. Nuts are also installed on the L5 pedicle screws, but tightened gradually, while distraction forces are gently applied to both rods (Fig. 83.6) under motor evoked potential (MEP) and/or

sensory evoked potential (SEP) monitoring. Combined EMG, SEP, and MEP monitor is advocated in SDSG. Some authors have indicated that too much distraction force may injure the L5 nerve root because of excessive tension. This maneuver eases the reduction of the L5 vertebra, which has slipped anteriorly with a rotatory movement, and widens the foraminal space. Recently, a spondylolisthesis reduction instrument that can lift the L5 using cycloid force became available for cases of severe slippage (Fig. 83.7). Regardless, the reduction maneuver can potentially injure the nerve root. Therefore, careful neurophysiological monitoring and visual inspection of the L5 nerve root are mandatory.

Fig. 83.7: A spondylolisthesis reduction instrument can lift L5 using cycloid force.

Fig. 83.8: After interbody cage insertion, compression force is applied.

8. After the correction, disc resection is performed again. The rounded S1 superior end plate is removed by an osteotome. Interbody cages made of titanium alloy or polyetheretherketone are inserted bilaterally. The intervertebral space is filled with iliac crest autograft. Finally, compression force is applied to obtain lumbar lordosis between the L5 and S1 pedicle screws (Fig. 83.8). After reduction, it is usually easy to observe the L5 nerve root, which should be carefully checked for foraminal impingement.
9. After surgery, the patient is kept in a supine position for 2 or 3 days and wears a hard brace for 8-12 weeks.

CASE PRESENTATION

A 41-year-old woman complained of persistent low-back pain and severe bilateral thigh pain for 1 year. She had had occasional low-back pain in her late teenage years. The clinical symptoms had been relieved by conservative treatment with a brace and analgesics. However, the pain had worsened, and she was unable to stand without assistance at the initial visit.

She complained of low-back pain and left buttock to posterior thigh pain when standing and at rest. There was severe tightness of the hamstrings. There was no motor or sensory deficit or pathological reflex, but she had experienced some episodes of frequent urination. The preoperative Japan Orthopaedic Association (JOA) score was 17/29.

Fig. 83.9: A 41-year-old woman complained of persistent low-back pain and thigh pain. Radiography revealed high-grade spondylolisthesis (slip angle: 38°, slip percent: 63%).

The radiographs revealed high-grade spondylolisthesis (slip angle: 38°, slip percent: 63%) (Fig. 83.9). Monosegmental fusion and reduction with neuromonitoring and image guidance was performed. No operative complications, including nerve root impairment, occurred. The operation time was 4 hours and 45 minutes. The estimated blood loss was 360 mL. Postoperatively, the low-back pain and preoperative neurological deficit had resolved, and the JOA score improved to 25/29. The slip angle was corrected to 3°. The percent slip was corrected to 3% (Fig. 83.10).

Fig. 83.10: The L5-S1 fusion with reduction was performed. Percent slip was corrected to 3%.

KEY POINTS

- Surgical treatment for high-grade spondylolisthesis is challenging.
- Precise instrumentation and neuromonitoring are necessary in the surgical treatment of high-grade spondylolisthesis.
- Wide laminectomy and exposure of the L5 nerve root are needed to avoid intraoperative nerve root impingement.
- The slip should be reduced to within 25% and the slip angle should be restored as much as possible.
- Monosegmental fusion using a modern pedicle screw system and interbody cage enables favorable correction and fusion.

INTRODUCTION

Hu et al. found an average annual incidence of 64 patients with a thoracolumbar spinal fracture per 100,000 with an annual hospitalization rate of 29 per 100,000 in Manitoba, Canada.¹ An epidemiological study performed in Sweden showed an incidence of thoracolumbar fractures of 30 per 100,000 inhabitants per year. When patients older than 60 years were excluded, the incidence was 13 per 100,000. The most frequent causes were transport accidents and falls from heights.² A large epidemiological study in China between 2001 to 2007 showed that 4.58% of all traumas were thoracolumbar spinal fractures, with an annual increase in incidence each year. The two most common causes of injury were traffic accidents and falls from height.³ A review on road traffic injuries shows that in high-income countries, the number of lives lost in road crashes indicates a downward trend. On the other hand, the best available evidence suggests that in low-income and middle-income countries, the incidence of road traffic injuries is higher and still growing. Using the best available evidence, the World Bank report estimates that there will be a 28% reduction of fatalities in high-income countries in the next 20 years, while India and China will show an anticipated rise of 92% and 147% of traffic road casualties. Still, estimates are unreliable so far.⁴ The most vulnerable road users are pedestrians, cyclists or users of motorized two-wheelers according to a road traffic report from the World Health Organization.⁵ Together with the rising

incidence of road traffic injuries, the incidence of spinal fractures will proportionately rise. Because spinal fractures have a poor outcome compared with other major injuries, prevention of these traumas is important and policy makers should be aware of this.

DIAGNOSIS

Dependent of trauma cause, patients with a possible spinal fracture are presented at an emergency department on a spine board. After primary Advanced Trauma Life Support (ATLS) survey and stabilization of the spine, the patient is examined by a log roll and inspection of the back. A comprehensive neurological examination should always be part of the physical exam and be recorded, preferably using the systematic approach proposed by the American Spinal Injury Association (ASIA).⁶ Then standard plain film radiography is performed. In polytrauma patients, a Spiral Computed Tomography (SCT) scan is in most hospitals the standard procedure to examine thorax, abdomen, pelvis and spinal injuries as well. On a plain radiography, 25% of burst fractures are misdiagnosed as compression fractures.⁷ A study by Venkatesam showed that especially patients with a high Injury Severity Score, a low Glasgow Coma Scale and hemodynamic instability were most likely to have a thoracolumbar fracture without typical clinical findings and would benefit most from SCT. They also showed that in 303 blunt torso trauma patients, 3.6% of the patients had severe thoracolumbar spinal

fractures without evident clinical findings. This may be due to patient factors but also because of junior staff members performing physical examination.⁸ Further, the sensitivity of SCT detecting spinal fractures is 100% compared to 70% in plain film radiography and, on the contrary of what is expected, the radiation dose in thoracolumbar spine is lower with SCT (13 mSv compared to 26 mSv) than with plain films. SCT is far more costly than plain film radiography but there is a similar mean overall spinal imaging cost per patient (\$172 vs \$164) when time in the radiology department is considered.⁹

Magnetic Resonance Imaging (MRI) is more frequently performed in cervical injuries and may be indicated in certain cases of thoracolumbar trauma. Besides the cases with neurologic deficit, MRI is also helpful to evaluate the integrity of the so-called posterior ligamentous complex (PLC) (supraspinous and interspinous ligaments, ligamentum flavum, facet capsules and thoracolumbar fascia), which is an important factor for decision on treatment. The sensitivity of MRI for diagnosing injury of the various components of the PLC ranged from 79–90%. The specificity ranged from 53–65% with a positive predictive value of 70–78% and a negative predictive value of 50–88%.¹⁰ In patients with an ASIA score of A–C, the predictive values were higher and Vaccaro concluded that the integrity of the PLC should not be used in isolation to determine treatment.¹⁰

Three-dimensional CT can show more details of posterior element injured, which is the indirect sign of PLC. The most widely used sensitivity series of MRI is T2 short tau inversion recovery (STIR) or FAT SAT sequencing. Missed STIR scan sometimes may miss PLC injury, which contributes to prevent secondary kyphosis after anterior column injury.¹¹

CLASSIFICATION

More than 60 different classification schemes have been reported in the literature. The comprehensive classification scheme proposed by Magerl et al.¹² is the most systematic scheme for a general understanding of the injury types. In this scheme, there are three basic types of injury:

- **Type A:** Injury to the anterior elements (vertebral body and the discus) predominantly by compression forces. The posterior tension band is intact. Sub-classification:
 - **A1:** Wedge-compression of the endplate
 - **A2:** Split fracture of the vertebral body
 - **A3:** Burst fracture – fracture of the endplate with involvement of the canal.
- **Type B:** In addition to injury to the anterior elements, there is also failure of the posterior tension-band.
- **Type C:** As a result of injury to the anterior and posterior elements, there is a displacement/dislocation (Fig. 84.1).

Fig. 84.1: Basic types according to the AO Classification. Type A fractures compression injuries of the anterior elements with intact posterior tension band. Type B fractures with ruptured tension band. Type C fractures dislocation and rotation.

The Spine Trauma Study Group (STSG) has developed a thoracolumbar injury severity and classification system (TLICS), which can be used to decide on the most appropriate treatment.¹³ The following items are evaluated and points are assigned:

- **Morphology:**
 - Compression 1 point
 - Burst 2 points
 - Rotation/translation 3 points
 - Distraction 4 points
- **PLC (posterior ligamentary complex = tension-band):**
 - Spinal cord/conus
 - Intact 0 point
 - Suspected 2 points
 - Disrupted 3 points
- **Neurology:**
 - Intact 0 point
 - Root 2 points
 - Spinal cord/conus
 - Complete 2 points
 - Incomplete 3 points
 - Cauda equina 3 points

The sum of the points from each of these three items makes the total TLICS score.

The treatment algorithm proposed by the STSG:

- TLICS score 1–3: Conservative
- TLICS score 4: Operative or conservative
- TLICS score 5 or more: Operative.

Clinical modifiers such as polytrauma, ankylosis of the spine or the degree of deformity may add up to the basic TLICS score in the decision for conservative or operative treatment.

■ CONSERVATIVE TREATMENT

History

The conservative treatment of spinal fractures has a long history and the first written records date from 3,000 BC with the description of a cervical spinal dislocation with neurological impairment in the Edwin Smith Surgical Papyrus from ancient Egypt. There is also an incomplete description of a thoracolumbar fracture treatment advice in this manuscript. Between these and the writings of Hippocrates (460–377 BC) there are no written documents about spinal injuries. Hippocrates describes two methods

of treatment: shaking on a ladder and traction of the spine on a special bench, his preferred method. In the Middle Ages, the Islamic surgeons Ibn Sina (Avicenna) and Abu Al-Qasim (Abulcasis) continued the Hippocratic tradition. In the modern times, there was growing attention for the treatment of spinal injuries, and in the second half of the 19th century, splinting of the spine was introduced for the prevention of deformity. The last decade of the nineteenth century witnessed a milestone in the diagnosis and treatment of spinal fractures by the development of the ‘X-rays’ by Röntgen in 1895. In the first half of the twentieth century, Lorenz Böhler, a German military surgeon wrote his famous book on traumatology “Techniek der Knochenbehandlung”. He proposed a standard treatment for all thoracolumbar fractures based on “Einrichten, Festhalten, Üben” (reduction, immobilization and exercise). Reduction of the fracture was performed by hyperextension, and then a plaster of Paris corset was applied in this position for immobilization. The treatment was continued by a standardized training program to avoid muscle loss and improve psychological well-being.¹⁴ Watson-Jones,¹⁵ an influential British trauma surgeon, subscribed and popularized the ideas of Böhler in the 1940s, although there was some evidence also in that time that a good clinical result did not always correlate with a good anatomical reduction as reported by another British surgeon, Nicoll in 1949.¹⁶

Present

Although conservative treatment of thoracolumbar fractures seems to be a good established treatment modality nowadays, there are still numerous controversies in the literature. One of the major causes for this is that reliable evidence based on good clinical research in spinal trauma patients is still lacking. First of all, there is no agreement on what constitutes a good outcome in spinal trauma patients, especially for those without neurologic involvement. Little work has been done on developing and validating outcome assessments in spinal trauma patients.

While many surgeons agree that patients with neurologic involvement or severe mechanical instability, such as fracture-dislocations, should be treated operatively, spinal fractures categorized as Type A, according to Magerl Classification, may be managed non-operatively—these commonly include the anterior wedge and burst type fractures with intact PLC.

Fig. 84.2: Wedge compression fractures (A1 according to the AO Classification). Fracture of a single endplate without involvement of the posterior wall of the vertebral body. The vertebral canal is intact.

Anterior Wedge and Split Fractures

Nonoperative treatment for anterior wedge-compression (A1) and split (A2) type spine fractures is considered to be safe with an acceptable long-term outcome concerning pain, employability and residual deformity for the majority of patients (Fig. 84.2).

Treatment options vary from bed rest, the use of various orthoses, to functional treatment with postural instructions by physiotherapists. However, there is no consensus in the literature about the optimal management. There is also a paucity of evidence of the effectiveness of any of these different treatment schemes. Various authors concluded that it is not necessary to wear a brace, as this provided no additional therapeutic benefit.^{17,18} Gertzbein in his multicenter spine fracture study saw that after 1 year follow-up patients with a kyphotic deformity of $> 30^\circ$ had an increased incidence of moderate to severe pain.¹⁹ This report seems to be of influence in all further clinical research in the sense that conservative treatment of spinal fractures is reserved for fractures with an initial kyphotic deformity of $< 30^\circ$. The question is whether these patients had only simple wedge-compression fractures or also unrecognized PLC injuries, and were thus actually surgical candidates. Schnake et al. reported that 29% of all type B1 injuries cannot be detected on the X-ray or CT scan in his retrospective study.²⁰ It was argued that if there is $> 50\%$ loss of anterior vertebral height acutely, this may be suggestive of posterior element disruption and, therefore, should be an indication for further investigation.²¹ Despite these

reports and the practice to treat compression fractures usually with 'benign neglect', every spine surgeon knows cases of dissatisfied patients with substantial residual pain after different kinds of nonoperative treatment schemes who occasionally require operative intervention. The reason for this persistent severe pain after relatively minor injuries is not clear. Damaged discs and facet joints may be the pain generators. In split (A2) fractures, avascular necrosis of the anterior part of the vertebral body can occur. However, there is no reliable evidence in the literature on the specific prognosis of these injuries. Whether the disturbance of sagittal balance plays a role is not properly studied yet.

Therapy

The primary goal of treatment for patients with a spinal fracture is to protect the neural tissues and create an environment for optimal functional recovery with minimal pain. Further, the treatment should be cost-effective on the short, but also on the longer term. The majority of the victims are young people indicating that longer-term costs to the society with residual disabilities may be substantial. For wedge-compression fractures, it is not clear whether any active treatment except proper pain management is indicated. There are multiple braces, such as custom-molded total contact orthoses (thoracic-lumbar-sacral-orthosis—TLSO) or prefabricated stiff or elastic braces, which can be used for temporary immobilization. Various authors looked at the effect of braces on the immobilization of the spine. The advantage of a custom-molded cast or TLSO is that it distributes forces over a large surface area, improves fixation of the pelvis and thorax and controls lateral bending and axial rotation (Figs. 84.3 to 84.5).

This is most effective in immobilizing the spinal column.²² The prefabricated Jewett brace has no pelvic support and, therefore, lateral and axial rotations are not prevented (Fig. 84.6).

This brace is, thus, only indicated for fractures that are caused by flexion injuries like a wedge-compression fracture. The level of fractures for which this brace is recommended is from T6 to L3 with emphasis on the thoracolumbar junction.

Outcome of Anterior Wedge Fractures

There is one randomized clinical trial comparing physical therapy, a thermoplastic removable brace and a plaster cast for 6 weeks. Patients with less than 50% loss of

Fig. 84.3: Lumbosacral orthosis.

Fig. 84.4: 3-point orthosis.

Fig. 84.5: 4-point orthosis.

Fig. 84.6: Jewett brace.

anterior height were included. In this study, some type of immobilization was found to be better than physical therapy alone, considering Oswestry Disability outcome and Visual Analog Scale (VAS) pain score after an average follow-up of 7 years.²³ In this study, 18% of patients complained of moderate to severe persistent pain. Folman performed a retrospective analysis of patients with a thoracolumbar fracture (T11-L2) with at least 3 years' follow-up. Half of the patients were treated with a 3-point brace for 5 weeks and half with physical therapy. In this group, mild to moderate chronic low back pain was reported in 69% of cases and 25% had changed jobs, mostly full-time to part-time. These authors could not

find any effect of immobilization on the long-term on clinical results.²⁴

Karjalainen looked at patients treated with or without an extension brace ($n = 21$ vs 105 patients) after 7 years. There was no difference in outcome concerning radiological or functional aspects. In the brace, 19% had a poor outcome, in the functional group 17%.²⁵

A systematic review in 2009 did not find any effect of bracing in 7 retrospective studies.²⁶

In summary, anterior compression fractures can be treated in a functional way, where physical therapy and/or a simple brace can be considered for initial pain management. If there is compression of the anterior part of the

vertebra of more than 50% or a kyphosis angle more than 30°, PLC injury should be excluded and, if present, operative treatment considered.

One should not forget that many of these patients end up with some degree of persistent back pain and disability even after these relatively minor injuries. This incidence is much higher than seen after comparable injuries to the extremities. Almost 20% of patients suffering from moderate to severe pain after a 'minor' injury of the ankle, knee or wrist would not be accepted as 'good results.' We should ask ourselves how we can predict these unsatisfactory results and whether we can prevent disability.

Burst Fractures

Burst fractures are characterized by failure of the endplate under compression causing a fracture with involvement of the posterior cortex of the vertebral body, leading to a loss of integrity of the spinal canal (Fig. 84.7).

There may be varying degrees of canal involvement and compression of the dural sac with possible neurologic injury. Most burst fractures occur at the thoracolumbar junction (T10-L2) probably because of the transition of the kyphotic immobile thoracic spine to the lordotic mobile lumbar spine.

Burst fractures can be 'incomplete' involving only a single end-plate or 'complete' with fracture of the whole vertebral body and both endplates. It is not clear whether this distinction between 'complete' and 'incomplete' burst fractures has any prognostic significance despite the weak evidence from studies using the 'load-sharing classification'.²⁷ Burst fractures can also be associated with injury

to the posterior tension band or posterior ligamentous complex (PLC). Many surgeons recommend that when PLC injury is present, operative treatment is the preferred method in order to prevent progressive deformity or worsening of neurology.^{13,28}

Therapy

There is no consensus on the proper treatment of burst fractures of the thoracolumbar spine without neurologic deficit or PLC injury. There is a high degree of variation in the practices between different countries and regions. The same kind of fracture can be treated surgically with circumferential fusion in one region, while it may get a conservative care even without using a brace in another. Lacking universal tools for classification and outcome, it is not at this moment possible to provide strong evidence-based recommendations on the treatment of these relatively common injuries.

Many different nonsurgical treatment methods have been described in the literature for treatment of thoracolumbar fractures varying from bed rest in a plaster cast to mobilization without a brace. In the early 20th century, conservative treatment of serious thoracolumbar fractures consisted of bed rest in a plaster cast for up to 3 to 6 months, a treatment method associated with many complications. With the writings of Böhler in 1929, the more functional treatment of thoracolumbar spinal fractures became popular with reduction, plaster cast immobilization and exercises.¹⁴ Nicoll in 1949 advised a protective plaster in the neutral position without attempting a reduction of deformity.¹⁶ In 1970, Holdsworth actually

Fig. 84.7: Burst fractures. Fracture of the vertebral body with any involvement of the posterior wall. Vertical fracture of the lamina is usually present and does not indicate a tension band failure. Varying degrees of canal encroachment by fracture fragments.

introduced the concept of ‘burst fracture’ and described it as a stable injury because of intact ligaments. He advised that patients should be immobilized in a plaster with bed rest for 8 to 12 weeks because these fractures were very painful.²⁹ In 1984, Denis treated 39 patients with burst fractures nonoperatively in body casts and reported that 17% of these patients developed neurological complications, an exceptionally high rate not reported in other publications. This publication was influential in the growing popularity of operative treatment.³⁰ All of these reports were retrospective case studies. Cantor was the first to report in 1993 on the results of a prospective study of 33 patients. Only 18 patients were available for follow-up. Their conservative treatment consisted of a total contact extension TLSO for 14–24 weeks and they restricted their inclusion criteria to less than 30° kyphosis and less than 50% loss of anterior height, an inclusion criteria commonly adapted afterwards.^{18,31} From then on, more prospective papers were published with various treatment options, like a hyperextension brace and mobilization³²; 4–6 weeks of bed rest followed by mobilization in a cast³³; reduction under sedation and application of a body cast used for 3 months and mobilization.³⁴ Also two randomized controlled trials comparing operative and conservative treatment were published. In the nonoperative arms, Wood treated patients with a TLSO or a cast after reduction of the fracture for 14 weeks and mobilization;³⁵ Siebenga gave patients a Jewett brace for 3 months.³⁶

Finally, in 2009, the results of a prospective randomized multicenter paper were published comparing a prefabricated TLSO for 8–10 weeks compared with no orthosis for the treatment of thoracolumbar spinal fractures,³⁷ which also indicated no difference in Roland-Morris Disability Questionnaire, pain, functional outcome, generic health-related quality of life, sagittal alignment, length of hospital stay, and complications.

As bed rest for burst fractures has not been reported in the last two decades, the spectrum of present-day nonoperative treatment options ranges from reduction (Fig. 84.8) of the fracture followed by immobilization in a cast for three months to a mere functional treatment without any external support.

Outcome of Burst Fractures

Before discussing the outcome of conservative treatment of TL fractures, one should realize that there is no universally accepted way of measuring the outcome of these injuries.

Fig. 84.8: Reduction of fracture.

There is no consensus among the experts on the question of how a good or poor outcome should be defined. Little work has been done on developing and validating outcome assessment instruments in spinal trauma patients. Studies investigating outcomes in (spinal) trauma patients typically use a combination of several outcome measures, or improvise their own measures. Outcome reports in spinal trauma, therefore, should be interpreted cautiously.³⁸ Outcome in trauma patients is relevant in the short-term considering the duration of pain and return to work and other social activities. But also the change in the global spinal sagittal balance may be an important factor in the longer term. These are parameters not studied properly yet. Regional kyphosis angle was studied in the past as a possible critical parameter, but no evidence was found that regional kyphosis angle alone might be strongly related to clinical outcome.³⁹

Tropiano reported on the clinical outcome with reduction cast where 64% of patients did well considering pain, but 36% had moderate or severe pain after a mean follow-up of 3 years.⁴⁰ In a prospective study, patients with AO type 3 burst fracture and < 35° of kyphosis were randomized to treatment with or without a thoracolumbar orthosis. The primary outcome analysis at 3 month and after 1 year did not show any significant difference between the treatment groups with Ronald Morris Disability Questionnaire Scores of 6 and 7 respectively and VAS pain scores of 2.1 and 1.8.³⁷ As mentioned before, most studies performed are retrospective studies with follow-up periods of 1–2 years. Only a few studies mention long-term follow-up of 9 to 27 years.^{39–41} A study by Weinstein showed that after conservative regimens

varying from 3 months' bed rest to mobilization in a cast, 57% of the patients were never pain-free, although 88% returned to their former occupation, and none of them required narcotic medication after a mean follow-up of 20 years (11–55 years). A more recent study with a follow-up of 9.5 years related post-traumatic kyphosis angles to sagittal balance parameters. The patients who could not compensate their kyphotic deformity by increasing their lumbar lordosis and had to straighten other adjacent levels had worse clinical outcome. In this series, 62% of the patients did well while 38% had a fair or poor outcome. Also 19% of patients were not able to return to their previous employment, which is comparable with other studies.⁴¹ Another study reported results of burst fractures, treated in a range of direct mobilization to bed rest, where 22% of patients complained of moderate to severe pain after a follow-up of 27 years (range 23–41 years).⁴²

There is no evidence that nonoperative treatment may frequently lead to neurological deterioration. There is one exception, the report by Denis, where 17% of patients developed neurological complications.³⁰ It is not clear whether these patients had only burst fractures with intact PLC or more serious kind of injuries. Overall, nonoperative treatment is safe and, even in cases with some neurological symptoms, improvement has been reported.^{31,39,40,43}

List data of neurological functional improvement in burst fractures would be more persuasive. Dai reported neurological improvement with conservative treatment in Denis B-type burst fractures. Significant correlation ($P < 0.05$) was found between the load-sharing score on admission and the lost of local kyphosis angle at the final follow-up.⁴⁴ There are three reviews on the conservative management of thoracolumbar burst fractures published to date. Four studies are included in the first review: two RCTs, one quasi-RCT and one controlled clinical trial. Pooled data at follow-up showed mean VAS scores of 2.2, mean Roland Morris Disability Scores of 5.8, and return to work rates of 67%.⁴⁵ The other review included also 'unstable' fractures and compared nonoperative treatment with operative treatment. They concluded that this comparison was impossible with the current literature and higher quality randomized controlled trials are needed.⁴⁶ Dai wrote a comprehensive review in 2007 and concluded that in thoracolumbar burst fractures without neurological impairment, there is no superiority of conservative therapy over operative therapy.⁴⁷

In summary, many ways of nonoperative management of thoracolumbar burst fractures have been described

without any evidence of superiority of one scheme over the others. Bed rest is no longer advocated except may be for the first day(s) as pain relief. The need for closed reduction of the fracture is controversial, as is additional bracing. Closed reduction is difficult to maintain and there is no evidence for a significant effect on the long-term. Although there are concerns about the effect of post-traumatic kyphosis on the sagittal balance there are no guidelines on the degree of acceptable deformity. Concerning the immobilization, there is no consensus on the use of a cast, brace or TLSO or the duration of this treatment. Any kind of immobilization should be essentially seen as part of pain management. In general, the recommendation is a short period of bed rest if necessary, followed by some kind of brace for the first week during mobilization. As some of the PLC injuries can go undetected, it is advisable to obtain standing radiograms in this period. If progression of deformity is seen, surgical intervention should be considered.

FUTURE RESEARCH

First of all, there is much confusion on the classification of the traumatic injuries of the thoracolumbar spine, which prevents comparison of the results of different groups. A simple and reliable universal classification scheme would enable communication and research on the treatment and outcome. Little work has been done to date on the development and validation of outcome assessment in spinal trauma patients. Most studies have either assessed spine injuries from the critical care perspective or focused solely on spinal cord injury (SCI) from the standpoint of rehabilitation medicine. Studies that do investigate outcomes in (spinal) trauma patients typically have to resort to a combination of several outcome measures, or improvise their own measures. A proper spinal trauma injury outcome tool should be a simple and universal focusing on resumption of activities in comparison to pretrauma level of functioning. The spine community should concentrate on developing such a tool in the near future to adequately measure outcome in spinal patients.

Further, the debate about optimal management of thoracic and lumbar fractures continues among spine surgeons. New methods of clinical research should be considered and implemented. As shown in the two RCTs comparing operative versus nonoperative treatment of burst fractures, proper randomization of trauma patients is difficult because of different emergency-related factors leading to

strong selection biases and inadequate power to answer primary questions. Alternative methodologies should be developed to perform research on the outcome of trauma patients. One of the possibilities is the surgeon equipoise method recently suggested for these patients.⁴⁸ As spine registries are becoming popular, the spine community should also consider the trauma patients besides the degenerative and deformity cases in the design of these registries, and the proper research methodology.

KEY POINTS

- The incidence of spinal fractures in low- and middle-income countries will probably rise because of an increase in road traffic injuries. Because spinal fractures have a poor outcome compared with other major injuries, prevention of these traumas is important and policy makers should be aware of this.
- Spiral Computed Tomography shows 100% sensitivity for detecting spinal fractures compares to 70% on plain radiography films. MRI should be used when neurological impairment is present or PLC injury is suspected.
- Anterior compression fractures can be treated in a functional way, where physical therapy and/or a simple brace can be considered for initial pain management. If there is compression of the anterior part of the vertebra more than 50% or a kyphosis angle more than 30°, PLC injury should be excluded and, if present, operative treatment considered. For burst fractures, the recommendation is a short period of bed rest, if necessary, followed by some kind of brace for the first week(s) during mobilization and PLC injury should be excluded.
- There is no consensus on the use of outcome measurements in trauma patients with a spinal fracture. Therefore, good outcome is not defined. In the near future, a proper spinal trauma injury outcome tool should be developed, which is simple and universal, focusing on resumption of activities in comparison to pretrauma level of functioning.
- Appropriate randomization of trauma patients is difficult and alternative research methods should be developed to perform research in trauma patients.
- These patients should be included in patient registries to be able to compare treatment outcome, which leads to evidence-based treatment of these complex patients.

INTRODUCTION

Fractures of the thoracic and lumbar spine occur in approximately 6% of patients involved in blunt trauma, with the majority of these injuries occurring at the thoracolumbar junction (T12–L1). The aim of treatment, both nonoperative and operative, is to maintain spinal alignment and stability, preserve neurologic function, and minimize complications. Understanding these basic principles helps us to define the indications for surgery and subsequent management of thoracolumbar injuries.

EPIDEMIOLOGY

The incidence of spine fractures (9–22 cases/1,000 people/year) is stable, but the mechanisms of injury and the patient demographics have shown some changes over the years. Higher energy mechanisms typically affect younger patients, while the elderly with poorer bone quality sustain lower energy injuries. The majority of high-energy injuries occur as a result of motor vehicle collisions and falls from a significant height. Other mechanisms include sports and thrill-seeking activities. Concomitant spine injuries at noncontiguous levels occur in approximately 15% of thoracolumbar fractures. As our general population ages, low-energy injuries become more prevalent, resulting in osteoporotic vertebral compression fractures (OVCF).^{1,2} Roughly 25% of OVCFs present with significant pain

initially, and most can be adequately managed conservatively.³ Treatments of high-energy injuries differ based on the mechanism of injury, fracture pattern, soft tissue injury, and neurologic injury.

ANATOMIC CONSIDERATIONS

The thoracolumbar junction, T11–L2 spinal levels, is particularly susceptible to injury because of some specific anatomic features. Its costovertebral articulations and coronally oriented facet joints, which limit flexion and extension motion, stabilize the thoracic spine. This region of the spine is kyphotic (20–50°) with a relatively narrow spinal canal and therefore unable to accommodate more than minimal canal intrusion upon the neural elements.

Whereas the thoracic spine has greater axial rotation, the lordotic (40–80°) lumbar spine has more flexion and extension capabilities with sagittally oriented facet joints. The L3 vertebra is typically in a neutral position. The thoracolumbar junction represents a shift in the weight-bearing axis from a kyphotic, rigid thoracic spine to a lordotic, mobile lumbar spine with the fulcrum at the T12–L1 intervertebral disk, therefore making this region at higher risk for injury.

The adult spinal cord typically ends at the L1 vertebral body level and may be injured anywhere from the foramen magnum to the thoracolumbar junction. The spinal cord

is perfused by one anterior spinal artery and two posterior spinal arteries, which receive their supply from segmental radicular arteries and, in turn, from the posterior intercostal arteries. In a small percentage of patients, the artery of Adamkiewicz is the dominant anterior radicular artery that originates from one of the left T8–L2 intercostal arteries and therefore provides the major vascular supply to the anterior thoracolumbar spinal cord. An injury to this region may result in a significant vascular insult to the spinal cord.

CLINICAL EVALUATION AND MANAGEMENT

Primary responders should adhere to the systematic universal approach to all trauma patients in the field by securing the airway, ensuring adequate ventilation, and supporting hemodynamic status (ABCs). Patients with a spinal cord injury (SCI) may exhibit neurogenic shock, which is a circulatory collapse due to loss of sympathetic tones. This is identified by bradycardia associated with hypotension in the trauma setting. The patient is immobilized on a rigid backboard using in-line manual traction and a hard cervical collar before transportation. In order to initiate the appropriate algorithm of care, it is critical to appropriately identify the mechanism of injury and initial neurologic status. The patient should then be transported to the nearest facility with the necessary resources to treat acute traumatic spine injuries because optimal outcomes are achieved with a multidisciplinary team approach. In some cases, the trauma team can successfully manage thoracolumbar fractures nonoperatively if there are no dedicated spine specialists at the treatment facility.⁴

PHYSICAL EXAMINATION

The patient should be carefully logrolled into the lateral decubitus position with the cervical spine immobilized, while the back is thoroughly inspected for injuries including contusions, lacerations, tenderness, and step-offs. It has been reported that persistent localized tenderness after trauma to the thoracolumbar spine without obvious radiographic findings is indicative of the underlying occult spinal fracture in 30% of patients. A thorough examination of the neurologic system should include motor, sensory, reflex, and rectal examinations, documented using either the Frankel Impairment Scale or the American Spinal Injury Association (ASIA) form. Motor function is

assessed using the major muscles in the upper and lower extremities and graded on a scale of 0–5. Sensation is assessed in a dermatomal distribution including the perineal region because sacral nerve root sparing (detected by a normal sacral sensation or rectal examination) has been shown to be a positive prognostic factor for potential SCI recovery. The initial ASIA scale score has been shown to be a reliable predictor of long-term outcome in patients with cervical or thoracic SCI.

Injuries to the spinal cord above the level of the conus may result in spinal shock, which is a physiologic disruption of spinal cord-mediated function. This can cause complete absence of all motor, sensory, and reflexes below the level of SCI and typically resolves within 24–48 hours. Because the bulbocavernosus reflex is the first to return (it is the lowest cord-mediated reflex), this can be checked by brief traction on the Foley catheter or applying pressure on the penis or clitoris during a rectal examination resulting in sphincter contraction. If patients are in spinal shock, accurate assessment of neurologic function can only be made once it is resolved because many patients can have spontaneous recovery. Conus medullaris or cauda equina injuries can result in permanent loss of the bulbocavernosus reflex due to injuries of the lower motor neurons involved in the reflex—these patients are not in spinal shock.

In patients with multiple injuries, an altered level of consciousness, or head trauma, a more detailed imaging evaluation should be initiated. Certain patterns of injury such as multiple rib fractures, pulmonary contusion, widened mediastinum, abdominal bruising, visceral injury, and bilateral calcaneus fractures may indicate occult thoracic or lumbar spine trauma. In patients with associated spinal injuries, nearly half of these are missed on initial evaluation that could lead to neurologic injury or progression.

IMAGING

Plain radiographs of the spine should include orthogonal views and can provide a rapid means of screening for trauma including sagittal alignment; however, patients are typically supine, which can underestimate the degree of injury. Standing radiographs allow for weight bearing, which often worsens alignment. A loss of anterior vertebral height >50% suggests significant posterior ligamentous complex (PLC) injury. On the anterior-posterior view, coronal alignment can be assessed. Increased interspinous

Fig. 85.1: Sagittal computed tomography demonstrating the ankylosed spine with an extension-type fracture. This shows the ankylosed spine behaving like a long bone rather than a multiarticulating system of complex joints.

process distance suggests a flexion-type injury, while increased interpedicular distance suggests a burst fracture. A misaligned spinous process may be a rotational injury and focal scoliosis suggests an unstable injury.

Notably though, current literature has moved us away from plain films because of delays in care and inaccuracy in diagnosis.⁵ Advanced imaging modalities, such as magnetic resonance imaging (MRI) or computed tomography (CT), were once reserved to detail injury morphology after screening plain films, but now most trauma protocols use rapid screening helical CT scans of the head, thorax, abdomen, and pelvis during a routine evaluation. The images can then be reformatted to visualize the cervical, thoracic, and lumbar spines. If an injury is detected during the screening process, dedicated 2–3-mm cut axial images of the spine can be obtained and reconstructed. When using plain radiographs, injuries are typically missed in patients with ankylosing spondylitis or obesity and in those patients with fractures at the cervicothoracic and occipital–cervical junction. The CT provides for increased sensitivity, specificity, and predictive value in detecting spinal injury compared with plain radiographs.^{5,6}

CT imaging and its reconstruction formats enable evaluation of canal encroachment and overall alignment (Fig. 85.1). Recently, two studies sought to measure the deformity associated with thoracolumbar fractures with different imaging techniques. The first study looked at the measurement of kyphosis between plain radiographs, CT,

Fig. 85.2: Increased signal in T2-weighted magnetic resonance imaging images at the posterior ligamentous complex represents injury to the posterior stabilizing elements, signifying a more unstable fracture pattern. This injury includes disruption of the supraspinous ligament, ligamentum flavum and the less robust interspinous ligament.

and MRI. The authors found that Cobb angle measurement, Gardner segmental deformity angle, and anterior body compression percentage are reliable measures of thoracolumbar fracture kyphosis with very high interobserver and intraobserver reliability and very high intermodality agreement of plain X-ray with CT.⁷ The second study compared CT scans and plain radiographs in the acute setting and found an average mean difference of -1.13° in the sagittal plane and 0.10° in the coronal plane, resulting in interobserver correlation coefficients among the four observers of 0.913 and 0.953, respectively. Their research therefore found excellent interobserver correlation.⁸

An MRI complements the CT evaluation by assessing the nonosseous structures including the intervertebral disks, ligaments, and perhaps most importantly, the neural elements. Indications for obtaining an MRI include patients with altered mental status or neurologic dysfunction. Visualization of neural element injuries such as the spinal cord may be helpful in predicting neurologic recovery.⁹ Spinal cord hemorrhage and edema, indicated by a bright signal on T2-weighted images, is generally a poor prognosis.^{10,11} An MRI is also useful for detecting ligamentous injuries, especially the posterior structures (Fig. 85.2).^{12–15} This leads to a better understanding of injury severity including spinal instability necessitating possible surgery. A PLC injury indicates damage to one

or more of the following structures: supraspinous ligaments, interspinous ligaments, ligamentum flavum, and facet capsules. A recent study compared a surgeon's and a radiologist's assessment of PLC injuries by MRI. The researchers found that the surgeon was more accurate in interpreting injuries to some PLC components, but the relatively low positive predictive value and specificity for MRI in assessing PLC integrity suggests that both the surgeon and radiologist tend to overdiagnose PLC injury using MRI. This can lead to unnecessary surgeries if only MRI is used for treatment decision making.¹⁶ Disruption of the intervertebral disc similarly can mean injury to the anterior longitudinal ligament, the disc itself, and possibly the posterior longitudinal ligament (PLL). This can be seen as bright signals on T2 images and typically portend a more unstable fracture pattern. Finally, MRI is useful in visualizing bony edema that may be indicative of an occult fracture contributing to preoperative considerations on levels of fixation.

INJURY MECHANISMS AND SPINAL STABILITY

Axial Compression

An axially directed force through the vertebral body may result in fracture of one or both endplates as well as the body itself. A compression fracture is a failure of the anterior column, while a burst fracture also involves the middle column. The amount and trajectory (i.e. sagittal alignment) of axial load may determine column involvement, where the likelihood of a compression fracture increased with a flexion posture, while the chance of burst fracture increased with an extension posture. A more laterally directed force would result in compression on one side and tension on the other causing an asymmetric lateral wedge compression/burst fracture. The posterior column is more likely involved in these instances resulting in focal scoliosis with an increased risk of instability.

Flexion–Distraction (Chance Injuries)

The primary force of injury is distractive with the axis of rotation typically located just within the anterior column or anterior to the vertebral body producing tensile forces on all three columns. The axis can also occur through the middle column producing a compression or burst fracture

Fig. 85.3: Naked facet sign as seen on the axial computed tomography images where one of the facets is “empty,” which is indicative of a dislocated spine.

while distracting the posterior elements. A chance fracture is a failure of the bony elements, while its variants are purely ligamentous or both.

Flexion–Rotation

The most destabilizing force vector is torsional resulting in shearing of the middle and posterior columns while the anterior column collapses under compression. The involvement of all three columns makes this a very unstable injury that may be seen on anteroposterior (AP) plain radiographs as lateral translation. This may be part of the fracture–dislocation spectrum that is discussed later in this section.

Extension

Extension injuries result in failure of the anterior column in tension and compression through the posterior column. A variation is a distractive force through all three columns with potentially significant displacement. These are highly unstable shear-type injuries that are particularly seen in patients with conditions that cause ankylosis (Fig. 85.3) of the adjacent spine segments (i.e. diffuse idiopathic skeletal hyperostosis or ankylosing spondylitis).

Fracture–Dislocation

Fracture–dislocations are typically caused by a combination of force vectors as discussed previously resulting in disruption of all three columns through bony or ligamentous

elements or both. Therefore, there is a significant degree of spinal instability. Any degree of facet disruption, unilateral or bilateral, with possible vertebral body listhesis presents strong consideration of a fracture dislocation (Fig. 85.3). In some cases, the diagnosis is readily apparent with frank facet dislocation and translation of the cephalad vertebral body, while subtle in injuries in which there has been spontaneous reduction of the listhesis and minimal subluxation of a facet. A high index of suspicion is particularly important in those patients who present neurologically intact but have a subtle facet subluxation as this may be a highly unstable fracture dislocation that can quickly result in neurologic compromise.

Gunshot Injuries

Penetrating wounds from gunshots present another mechanism for thoracolumbar fractures that are usually inherently stable and rarely require stabilization. Plain radiographs and CT along with neurologic examination can characterize the injury. The use of MRI is controversial with the potential risk of bullet migration that has been reported, albeit rare.^{17,18}

Spinal Stability

The concept of spinal stability is predicated upon the maintenance of alignment and the prevention of neurologic deterioration. Treatment strategies have evolved with better understanding of the injury mechanisms and their propensity for early or late instability. This is particularly important at the thoracolumbar junction with its transitional anatomy from kyphotic to lordotic segments. The development of classification schemes has attempted to link different fracture characteristics to prognostic factors and hence guide treatment.

Early attempts at classification categorized spinal injuries primarily on morphology (disruption pattern) but lacked reliability in determining stability, while newer classifications attempted to be more inclusive (integrating mechanistic and biomechanical features); however, they were difficult to apply due to their complexity.^{19,20} The most recent attempt to guide treatment algorithm resulted in the thoracolumbar injury classification and severity score (TLICSS).

Thoracolumbar Injury

Classification and Severity Score

The Spine Trauma Study Group sought to incorporate the morphologic and mechanistic aspects of previous systems

Table 85.1: Thoracolumbar injury classification and severity score.

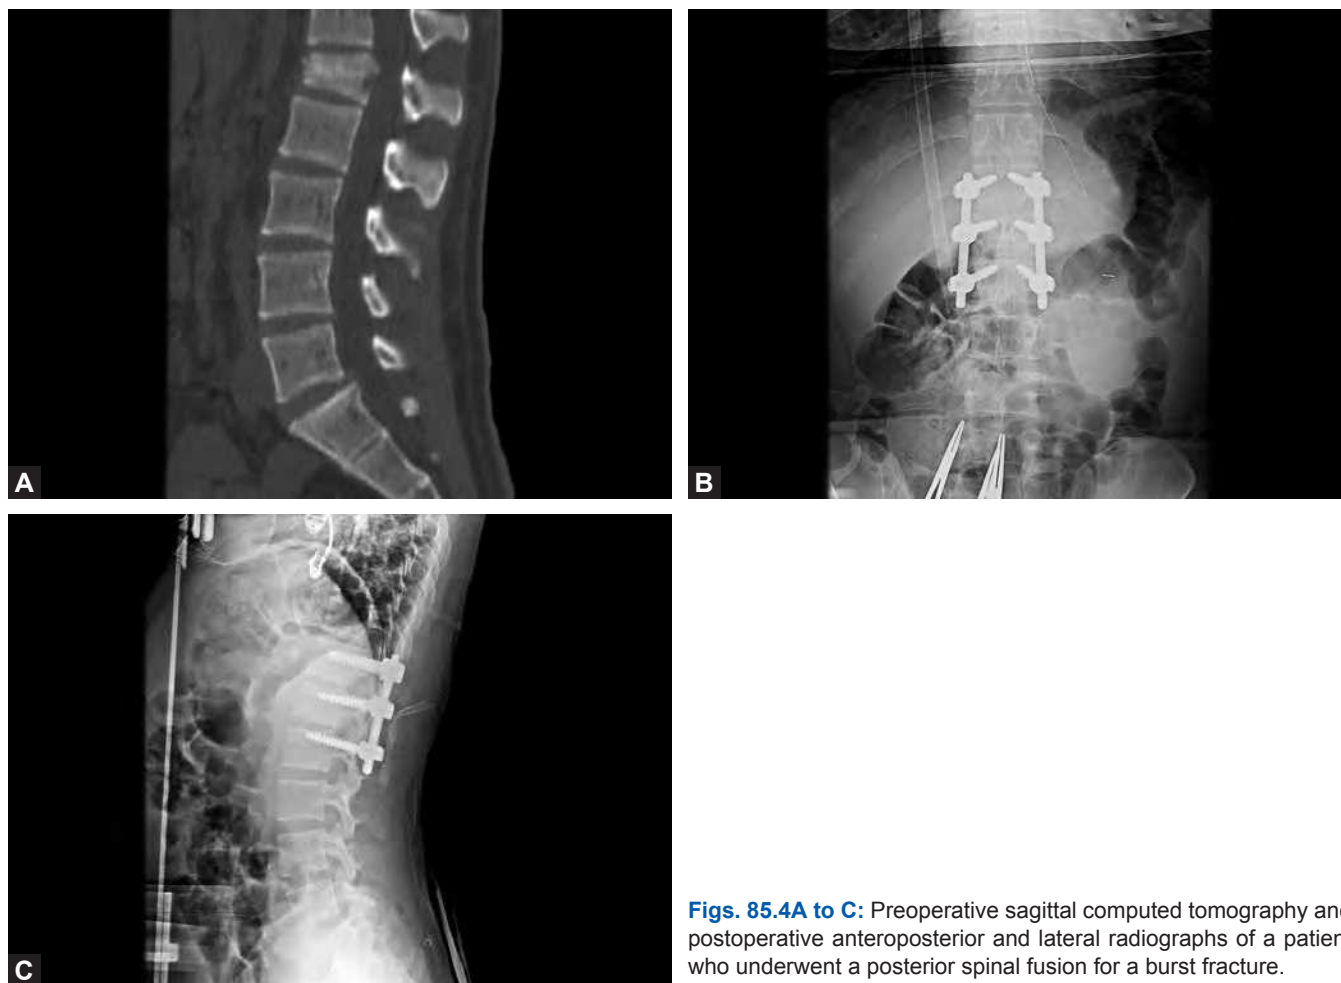

<i>Injury characteristic</i>	<i>Qualifier</i>	<i>Points</i>
Injury morphology	–	
Compression	Burst	+1
Rotation/translation		3
Distraction		4
Neurologic status		
Intact	–	0
Nerve root	–	2
Spinal cord, conus medullaris	Incomplete	3
	Complete	2
Cauda equina	–	3
Posterior ligamentous complex integrity		
Intact	–	0
Suspected/indeterminate	–	2
Disrupted	–	3

with neurologic status to determine stability and guide treatment.

In this system, stability assessment combines fracture morphology, neurologic injury, and PLC integrity (Table 85.1).^{21,22} Points are assigned based on the involvement of each criterion to tabulate a severity score for the patient to determine spinal stability and guide treatment (Figs. 85.4A to C).²³

Fracture morphology has been divided into compression, translation/rotation, or distraction to reflect the mechanism of injury in increasing severity, respectively. In the scoring system of TLICSS, neurologic injury indicates significant instability with incomplete injuries receiving a higher score. PLC integrity is assessed with fat-suppressed T2-weighted MRI with complete disruption likely requiring surgery.¹⁵ Significant instability is noted with a score >4 prompting surgical management, while a score <4 concludes that the injury is amenable to nonoperative measures. A score of 4 does not clearly indicate instability therefore treatment is at the discretion of the surgeon (Table 85.2).

Although this algorithm has not yet been validated by a prospective randomized study, several published papers have evaluated the reliability of TLICSS. In one paper, surgeons agreed with the TLICSS recommendation 96.4% of the time.²⁴ A study performed by an independent group of spine surgeons compared the reliability of the Denis, AO, and TLICSS classification systems and evaluated the skills necessary for their use. They found that the TLICSS system required a base level of knowledge and familiarity to be an acceptably reliable management tool when compared with the Denis and AO systems.²⁵ Another study

Figs. 85.4A to C: Preoperative sagittal computed tomography and postoperative anteroposterior and lateral radiographs of a patient who underwent a posterior spinal fusion for a burst fracture.

Table 85.2: Thoracolumbar injury classification and severity score treatment guide.

Management	Points
Nonsurgical	< 4
Nonsurgical/surgical	4
Surgical	> 4

attempted to validate TLICSS as a guide to management. In a retrospective review of 97 patients, the authors found that TLICSS consistently suggested management similar to past treatment recommendations. The most common exceptions to the TLICSS guidelines involved multilevel contiguous fractures and extension injuries in the ankylosed thoracic spine.²⁶

INDICATIONS FOR SURGERY

Treatment for thoracolumbar fractures can be divided into nonoperative (typically bracing) and operative measures.

Indications for surgery include neurologic compromise, mechanical instability, spinal deformity, and multiple associated injuries. In some cases, determining the appropriate indications is plainly obvious but not so in others, thereby requiring judgment by the treating surgeon. No standard algorithm exists in determining instability on initial presentation. Strong indicators for surgery include patients who have incomplete neurologic injury with significant kyphosis and canal compromise, fracture dislocation, and multiple noncontiguous spinal injuries. Relative indicators include burst fractures with PLC injuries, morbid obesity (and other comorbidities) that make bracing difficult, and multiple injuries that require frequent patient movement. The new scoring method using the TLICSS system may help despite the lack of validation in a prospective randomized study. The goals of any treatment (nonoperative or operative) are to maintain spinal alignment and stability, preserve neurologic function, and minimize complications.

Once the decision to operate is made, the timing of surgery must be considered especially in the multiply injured patient. A systematic review of the literature attempted to determine whether early spinal stabilization (within 72 hours) in thoracolumbar spine trauma decreases morbidity and mortality, by analyzing articles published between January 1990 and December 2008. A total of 68 articles were initially screened, and 9 ultimately met the predetermined inclusion criteria. These studies demonstrated that early stabilization of thoracic fractures reduced the mean number of days on a ventilator, in an intensive care unit, and in the hospital. Early stabilization also reduced respiratory morbidity compared with late stabilization. Except for length of hospital stay, there were no other benefits of early stabilization of lumbar fractures. Based on the evidence available, the effect of early stabilization on mortality could not be determined, but patients with unstable thoracic fractures should undergo early (within 72 hours) stabilization of their injury to reduce morbidity.²⁷

■ OPERATIVE TREATMENT

Anterior Approach

A burst fracture with spinal canal compromise resulting in incomplete neurologic injury is an indication for anterior surgery. A fracture at the thoracolumbar junction may result in injury to the conus medullaris or cauda equina and therefore strong consideration should be made to decompress the canal by complete or partial corpectomy.²⁸ Stabilization can be done with either a cadaveric bone or a cage construct.

Anterior-only surgery can be considered in burst fractures without evidence of PLC injury. Kaneda et al. treated 150 consecutive patients with thoracolumbar burst fractures and associated neurologic deficits with a single-stage anterior decompression, strut grafting, and instrumentation, and achieved a fusion in 140 (93%) patients while 142 patients improved by at least one Frankel grade. The 10 patients with pseudarthrosis were treated successfully with posterior instrumentation and fusion.²⁹ Another study by Sasso et al. reviewed their treatment of 40 patients with anterior-only decompression and reconstruction, and found a 95% fusion rate with a mean improvement in kyphosis from 22.7° to 7.4°. They also found that 91% of their patients with incomplete neurologic injury improved by at least one Frankel grade.³⁰

Posterior Approach

The posterior approach is commonly used to stabilize thoracolumbar fractures (Fig. 85.4) and can be used to decompress as well via an indirect or direct approach. Pedicle screw instrumentation allows for a shorter segment construct compared with prior hook/rod constructs. Several studies have shown though that segmental instrumentation and arthrodesis only one level above and below the fracture yield a >50% failure rate, with resultant progressive kyphosis, loss of anterior vertebral body height or screw breakage.^{31,32} These clinical findings are supported in a review of biomechanical studies that showed increased stress on short posterior segmental instrumentation with loss of anterior column integrity.³³ Short-segment posterior fixation is indicated when combined with anterior column reconstruction or in fracture patterns with minimal anterior column loss. Otherwise, segmental stabilization should be done at two or more levels above and below the injury.

When the PLL is intact, indirect decompression can be done through ligamentotaxis of the fracture fragments via longitudinal distraction. This can be done in compression and burst fractures with an intact PLL, with one study showing an improvement of the mean canal cross-sectional area preoperatively of 49% of normal to 72% of normal immediately postoperatively and a mean cross-sectional area of 87% of normal at 5-year follow-up from remodeling.³⁴

Direct decompression can be done through a transpedicular approach, which would spare the patient from the morbidity of a separate anterior approach, but typically involves the considerable removal of the facet and lamina along with the pedicle. The removal of these posterior bony elements may further destabilize the spine leading to mechanical failure. In a retrospective study involving 28 consecutive patients with a thoracolumbar burst fracture, neural canal decompression was performed via the transpedicular approach, resulting in 82% of patients showing neurologic improvement but at a 17.8% pseudarthrosis rate.³⁵ In another study, anterior column support was performed through a posterior approach. The authors reviewed a consecutive series of 37 thoracolumbar fractures that were managed with three-column reconstruction through single posterior (TRSP) approach between May 2004 and September 2006 and observed them for a minimum of 2 years. The mean operative time was 157 minutes with a mean blood loss of 1086 mL. The average Frankel score improved from 3.46 to 4.46, segmental

kyphosis improved from 26° before surgery to 5° at the time of the last follow-up, and the loss of segmental height improved from a mean of 35% preoperatively to 7% at the time of the last follow-up. The TRSP approach seems to be a safe and effective option for treating unstable burst fractures.³⁶

Combined Anterior–Posterior Approach

Although there is no clear indication of when to do a combined approach, it is generally believed that loss of anterior column integrity with disruption of the posterior elements provides strong consideration for circumferential fusion (Figs. 85.5A and B). The obvious advantage of this approach is the enhanced mechanical stability of the construct at the expense of the morbidity of two separate approaches that can result in increased complication rates. In vitro studies have shown superior mechanical stability in the combined approach compared with a single anterior or posterior procedure,^{37,38} which has also been seen in retrospective studies with maintenance of kyphosis correction and less instrumentation failure.³⁹ Despite these positive results, there are no prospective studies to validate the combined approach for the different types of unstable thoracolumbar fractures.

Surgical technique—our preferred surgical technique for an unstable L1 burst fracture with conus injury—combined anterior–posterior approach—is as follows:

- Perform the posterior approach first with the patient placed on the Jackson table in the prone position.
- Use somatosensory evoked potentials (SSEP) monitoring for both approaches.
- Make a midline incision from the bottom of T10 down the L2–L3 junction.
- Expose the T11–L3 spinous processes, lamina, and transverse processes.
- Note disruption of the posterior bony and ligamentous elements.
- Place a Kocher at the L1 spinous process and confirm with a lateral X-ray.
- Harvest iliac crest bone graft through a separate incision.
- Insert pedicle screw instrumentation from T11 to L3 (do not place screws in fractured pedicles because there is not much bone purchase and increased risk of neurologic injury).
- Cut and bend appropriate rods into a lordotic posture.
- After placing the rods, apply a cross-link (typically at the fractured level).
- Burr the posterior elements from T11 to L3.
- Morselize the iliac crest autogenous graft and place along the posterolateral gutters.
- Place morselized local autograft and allograft along the lamina bilaterally.
- Obtain final intraoperative X-rays to ensure appropriate instrumentation positioning.
- Place a subfascial drain and then close in standard fashion.
- If postoperative CT reveals inadequate indirect reduction, perform an anterior decompression and instrumentation.
- The vascular team performs the thoracolumbar approach and provides access to the L1 vertebral body, which is confirmed with intraoperative X-rays.

Figs. 85.5A and B: Anteroposterior and lateral radiographs of a patient who underwent a posterior spinal fusion and corpectomy with expandable cage reconstruction for a burst fracture that had a conus medullaris injury.

- Retract the anterior one-third of the psoas muscle anteriorly and the remaining two-thirds posteriorly to allow visualization of the fractured L1 vertebral body.
- Take care to protect the aorta anteriorly and the nerve roots posteriorly while exposing the T12–L1 and L1–L2 disc spaces.
- Perform the discectomies using a 15-blade, Cobb, curettes, and pituitary rongeurs and then identify the T12 inferior endplate and the L2 superior endplate.
- Use an osteotome initially during the corpectomy to cut the L1 vertebral body into multiple fragments and then remove with a pituitary rongeur.
- Use a high-speed burr to thin out the anterior and posterior cortices.
- Use a Kerrison to transect the pedicle and allow exposure of the posterior aspect of the spinal canal.
- Identify the retropulsed fragment(s) and remove with a reverse-angled curette. This should allow complete anterior decompression of the spinal canal.
- Burr the T12 and L2 endplates to slight bleeding bone in preparation of cage placement.
- Place the expandable cage filled with local vertebral body autograft (and harvested rib during exposure) in the center of the corpectomy trough.
- Expand the cage to engage the endplates and then test its stability with the insertion handle (i.e. no movement of the cage).
- Thoroughly irrigate the wound and allow the vascular team to close the wound.

Nonfusion Stabilization Procedures

The concept of an internal brace without fusion for thoracolumbar fractures is gaining popularity in certain practices. The advent of percutaneous techniques has led to the adoption of these principles in treating thoracolumbar fractures in recent years. In a retrospective nonrandomized case-control study, the clinical and radiological results of a minimally invasive posterior technique were compared with conventionally open posterior surgery. Twenty-one consecutive nonrandomized patients with thoracolumbar vertebral body fractures without neurologic deficits were stabilized posteriorly without fusion between 1996 and 1997, and were followed up > 5 years postoperatively. Eleven patients were treated conventionally open, while 10 patients underwent the minimally invasive technique. The patients who underwent the minimally invasive surgery had significantly lower intraoperative blood loss.

There were no differences between the two groups in operative time, X-ray exposure, and the loss of correction. A correlation between the loss of correction and clinical outcome could not be demonstrated. When treating thoracolumbar fractures without neurologic injury, minimally invasive posterior stabilization can lead to lower blood loss in comparison to the conventionally open method.⁴⁰

Another retrospective study was undertaken to evaluate the results of posterior stabilization of thoracolumbar fractures using a nonfusion method (pedicle screw/rod fixation without fusion) and subsequent removal of metal implants after an appropriate time period postoperatively. Twenty-three patients under 40 years of age (mean, 28.0 years) with thoracolumbar or lumbar spine fractures underwent posterior stabilization without fusion. Implants were removed at a mean of 9.75 months (range: 6–17 months) after initial fracture fixation, and patients were observed for >18 months. Changes in the sagittal alignment of operatively fixed segments and the heights of vertebral bodies as well as the restoration of segmental motion (flexion–extension and right–left bending views) were measured. Clinical aspects, such as gross deformities and functional abilities, were also investigated. Heights of fractured bodies were well maintained at the final follow-up. Preoperative mean sagittal angle was 17.2° kyphosis, which improved to 2.8° lordosis after fracture fixation. Just before implant removal, the sagittal angle was 1.7° kyphosis, then 2.4° kyphosis immediately after implant removal, and 5.9° kyphosis at the final follow-up. Mean segmental motion was 14.2° in the sagittal plane and 13.1° in the coronal plane at the final follow-up. Most patients were satisfied with final gross appearance and functional outcome. The described nonfusion method seems to be effective in achieving favorable sagittal alignment and regaining motions of fixed segments. The present study suggests that the nonfusion method may be an effective option for managing thoracolumbar fractures, especially in young active people.⁴¹

SUMMARY

The goals of thoracolumbar injury treatment are to maintain spinal alignment and stability, preserve neurologic function, and minimize complications. We have gained an improved understanding of these injuries through evolving classification systems and imaging modalities. Early and accurate assessment of thoracolumbar injuries results in better management.

Advances in imaging capabilities as well as a more thorough evaluation of injury morphology, neurologic status, and PLC integrity have led to an improved decision-making process. When indicated, surgical treatment strategies (approach and construct) are based upon the pathomechanics of the injury. Ensuring fracture stability, whether operative or nonoperative, improves outcomes and patient satisfaction, and allows for earlier mobility.

KEY POINTS

- Thoracolumbar fracture treatment has evolved with improved injury description and classification.
- Early recognition of thoracolumbar injuries allows for accurate assessment of spinal stability and neurologic deficits.
- Treatment strategies remain controversial, but a new scoring system (TLICSS) improves the decision-making process on appropriate intervention.
- The principles of operative treatment include restoration of spinal alignment and stability, prevention of neurologic deterioration, and early mobilization of the patient.
- The incidence of vertebral osteoporotic compression fractures will continue to rise as our population ages, requiring constant vigilance regarding treatment strategies.

■ EPIDEMIOLOGY, BIOMECHANICAL AND ANATOMICAL ASPECTS OF LOWER LUMBAR SPINE FRACTURES

The annual incidence of spinal fractures is approximately 64 per 100,000 in the United States.¹ Common causes of spinal injuries are motor vehicle accidents (50%), falls from height (21%), violence injuries (11%), sports injuries (10%), and other reasons (8%). Due to anatomical and biomechanical characteristics of the thoracolumbar spine, the majority of thoracolumbar injuries are located between T10 and L2.² Lower lumbar injuries between L3 and L5 only account for a small percentage of thoracolumbar fractures (approximately 14%).^{3,4} Anatomically and biomechanically, the region of L3–L5 differs from other thoracolumbar areas. The L5 and sometimes the L4 vertebrae are stabilized by iliolumbar ligaments. The pelvis acts as an additional stabilizer against traumatic forces.⁵ The physiological lordosis of the region with the apex normally located at L3 leads to a load distribution that differs from other thoracolumbar areas. In contrast to the thoracolumbar junction, axial forces run through the posterior aspect of the vertebral bodies. Hence, traumatic axial compression forces produce uniform compression of the vertebral body not typically resulting in a kyphotic deformity.⁶ However, if a posttraumatic kyphosis occurs, it is difficult to compensate

and may lead to a global imbalance. It has been shown that restoration of the sagittal lumbar lordosis (L1–S1) to angles $>25^\circ$ is associated with an improved functional outcome after correction of painful posttraumatic kyphosis.⁷

Concerning possible neurological deficits in the lower lumbar spine, the following aspects have to be considered: The widest diameter of the spinal canal can be found in the lumbar region. There have been several reports of traumatic canal narrowing of as much as 90% in the cross-sectional area without a neurological deficit especially at L4–L5. The conus medullaris typically ends between L1 and L2 and the cauda equina behaves similar to peripheral nerves in terms of functional recovery.⁸ Possible risk factors for neurological deficits in the lower lumbar spine are the combination of severe spinal stenosis and disruption of the posterior ligamentous complex.⁹ The anatomical characteristics mentioned may help to explain the infrequency of severe neurological deficits and the potential neurological recovery when such a fracture is present.¹⁰

■ LITERATURE REVIEW

Looking at the literature there are limited studies about the treatment of lower lumbar vertebral fractures. Outcomes of conservative and surgical treatments were presented at these studies, but none of them has large series. Although

isolated L5 fractures are rare, many of these studies include cases only with L5 fractures. In conclusion, the level of evidence regarding the treatment of lower lumbar fractures is fairly low.

Chan et al. performed a retrospective view of 20 conservatively treated patients.¹¹ Patients suffered from lower lumbar burst fractures (L2–L5). None of the patients had neurological deficit at the time of injury. Total follow-up averaged 3.9 years. Average of kyphotic deformity increased meanwhile, but insignificantly, 90% of patients had a good to excellent outcome, 10% had fair outcome, 75% of the patients reported mild to moderate pain, but none of them was physically restricted due to pain. The authors concluded that conservative treatment should be the treatment of choice for lower lumbar fractures in patients without neurological deficits.

Lehman et al. operated 32 patients with lumbar burst fractures.¹² All of the patients were in military service and all suffered from combat-related spinal injuries. Nineteen of the included patients had lower lumbar burst fractures (L3–L5). Interestingly, patients who carried armors mostly had lower lumbar fractures. Though carrying armors lower the force in thoracolumbar junction, it transfers the force to lower segments. More than half of the patients had neurological deficits. Twenty-two of the patients underwent surgery. Postoperatively, neurological deficits remained in all but one patient. The authors recommended surgical treatment for high-energy lower lumbar spinal traumas.

Ramieri et al. reviewed retrospectively 19 patients with L5 burst fractures.¹³ Six patients had motor deficits and 12 patients had sphincter dysfunction. They performed posterior stabilization in 18 patients and a combined posterior–anterior stabilization in one patient. Pain relief was significant in most of the patients. Some of the patients recovered neurologically. Like most of the other spinal surgeons, the authors found anterior stabilization to be a difficult procedure. They suggested posterior stabilization in cauda equina syndrome and nerve root injuries. The authors also pointed out that posterior approach is sufficient for stabilization, decompression and restoring the sagittal profile of the spinal column for L5 burst fractures.

Sebesta et al. followed 11 patients with L5 burst fractures treated by posterior instrumented spinal fusion.¹⁴ Average follow-up was 18 months. They observed loss of vertebral height and loss of reduction with the development of a consecutive local kyphosis. Three patients had loss of lordosis by average of 9° because of broken screws. At the end of the study, all but one patient had pain and

neurological disorders. The authors concluded that good clinical outcomes were in contrast with radiological findings. They suggested that posterior stabilization is sufficient enough for treatment of L5 burst fractures.

In 2007, Butler et al. presented a study with 10-year follow-up of 14 cases with L5 burst fractures.¹⁵ They compared the results of conservative and surgical treatment. None of the patients had neurological deficits. Ten patients were treated conservatively and four patients underwent surgery. The authors reported better radiological outcome in the surgically treated group. In conservative group, loss of height and kyphotic deformity were more frequent. The authors advised for conservative treatment for patients with L5 burst fracture, who do not suffer from neurological deficit, major fragments in spinal canal, or severe bony deformity, respectively.

Studies comparing outcomes of surgical and conservative treatment are limited in the literature. In 1992, An et al. studied retrospectively 20 patients with lower lumbar burst fractures.¹⁶ Seven patients were treated conservatively and 13 patients underwent surgery. Both groups included patients with neurological deficits, but after treatment none of the deficits persisted. In the conservative group, there was 31% loss of vertebral height on average, but only 19% in the operated group. Furthermore, the resulting kyphosis of 9.2° on average was significantly higher in the conservative group. The authors suggested that in spite of radiological findings, conservative treatment should be chosen in neurologically intact patients with lower lumbar fractures. If case of surgery, they recommended short rigid fixation.

Another comparative study was published by Seybold et al.⁵ They retrospectively reviewed 42 patients that is one of the largest published series of lower lumbar burst fractures. Patients were treated between 1980 and 1996. Average follow-up time was 45.2 months. Twenty patients were treated conservatively and 22 patients surgically. Both groups consist of both neurologically intact and injured patients. At the end of the study, the authors showed that final functional status was similar in both groups. Looking individually at the level L3, L4 and L5, the authors could not find any significant difference in the long-term clinical results. In contrast, patients undergoing conservative treatment for L3 fractures developed greater loss of height and local kyphosis. Nevertheless, functional outcome in the conservative group was satisfying, so that the authors suggested conservative treatment as a viable treatment option.

CONSERVATIVE TREATMENT

It is a common standpoint that conservative treatment can be chosen in stable fractures with posterior ligamentous continuity and without neurological deficits.^{5,11,13,15-18} In doubt, MRI scan should be performed to rule out any injury of the posterior ligament complex that can be overseen easily.¹⁹ No consensus exists regarding the specific type of conservative treatment. Typically, treatment consists of pain medication, initial bed rest followed by mobilization with cast or brace. The authors recommend bracing with a rigid orthosis (e.g. Boston-Overlap-Brace) for 6–12 weeks, depending on the type of fracture. Patients should be followed closely and standing X-rays should be obtained after 1, 4, 12, 24, and 48 weeks, respectively. Increasing kyphotic or scoliotic deformity, together with ongoing pain are reasons to reconsider surgical therapy. Accompanying physiotherapy with strengthening of both, abdominal and lumbar muscles should be conducted. Occupational therapy is recommendable, especially in elderly patients.

SURGICAL INDICATIONS

The purposes of the surgical treatment are to remove any mechanical pressure from neural structures, to correct kyphotic deformity, to achieve anatomical reduction, and, most important, to obtain a stable and functional spine.

From the authors' point of view, any neurological deficit indicates surgical treatment, especially in unstable situations. In contrast to other regions of the thoracolumbar spine, neurological deficits may not only be due to the traumatic impact but also due to the persistent compression of the cauda equina or nerve roots, respectively. The decompression of the entrapped neurological structures may therefore reduce (radicular) pain and promote neurological recovery. However, we admit that currently no evidence exists regarding the effectiveness of surgical decompression. This fact has to be discussed with the patient before performing surgery.

Highly unstable fractures (B- and C-type injuries according to AO-Magerl³) are indications for surgical stabilization, too. This includes flexion-distraction injuries and fractures with dislocation. Special considerations that may stress surgical treatment are concomitant polytrauma, ankylosed spine, obesity, and osteoporosis, respectively.

There is an ongoing discussion about the treatment of burst fractures as described above. While incomplete

burst fractures (type A3.1 according to AO-Magerl³) can be treated conservatively in the majority of cases, burst split or complete burst fractures (types A3.2 and A3.3 according to Magerl³) can cause local kyphosis and unbearable pain. Therefore, the latter types can be treated surgically in selected cases.

SURGICAL TECHNIQUES

Surgical therapy involves stabilization of damaged motion segments and decompression of neural elements, if necessary. In case of greenstick fractures of the anterior cortex of the lamina or increased interpedicular distance, dural tears should be suspected. In such cases, any reduction maneuvers may entrap neurological structures. Therefore, decompression and exploration of the dural sac should be performed beforehand.²⁰ Posterior decompression can easily be performed by laminectomy and stabilization can be achieved with transpedicular screw fixation.^{17,21}

Stabilization can be done posteriorly, anteriorly, or combined. Posterior or/and anterior stabilization are options for the surgical treatment of thoracolumbar fractures, but in lower lumbar fractures anterior stabilization may be difficult because of the major vessels.^{13,22} Corpectomy, lateral plating, and vertebral body replacement with cage can be performed with anterior or lateral retroperitoneal approaches. Anterior column support is even possible from posterior via transpedicular bone grafting or cage implantation.^{17,23}

In cases of severe vertebral body comminution with marked kyphosis and persisting fragments in the spinal canal, a combined anteroposterior approach provides optimal stabilization and decompression while it reassures lumbar lordosis.¹⁰

Obviously, more aggressive surgery may inevitably lead to higher complication rates. The pros and cons have to be balanced and explained to the patients before performing surgery.

The majority of authors favor posterior surgery with short transpedicular constructs.^{5,13,14-16}

However, the treatment of choice may depend on regional characteristics and treatment recommendations. In a German multicenter study including 111 patients with lower lumbar fractures, 93% of patients underwent surgery, 57% were stabilized only from posterior, 41% underwent combined anterior-posterior stabilization and 2% were stabilized only from anterior, respectively.²⁴

Posterior Stabilization

In the lower lumbar spine, posterior stabilization should aim to save segments and mobility and therefore be as short as possible. Today, posterior stabilization is typically performed with internal fixators including pedicle screws.²⁵ Because of the high loads in the lower lumbar spine, the authors recommend the use of screws with 6-mm diameter whenever possible.²⁶ Furthermore, 6-mm titanium rods or 5.5-mm cobalt-chrome rods should be used to avoid rod failure. As one of the defined surgical goals is anatomical reduction, angular-stable internal fixators with monoaxial screw systems are advisable. Polyaxial screw systems are inferior concerning stability that have shown higher loss of correction in the postoperative course.^{27,28} Using the above-mentioned monoaxial angular-stable constructs, short fixation typically involving only two segments is possible in the vast majority of cases. Additional short pedicle screw insertion at the effected level can enhance the overall stability.²⁷

Recently, percutaneous stabilization has become popular in some geographical regions. Percutaneous stabilization leads to less soft tissue damage, but fusion is technically not possible.²⁹ Thus, percutaneous stabilization might be an alternative to brace treatment. Loss of reduction especially after implant removal is a typical risk of this treatment concept. However, in elderly patients with osteoporosis the authors recommend percutaneous polymethyl-metacrylate (PMMA)-augmented pedicle screw stabilization with or without additional kyphoplasty of the affected vertebral body.³⁰ In our experience, at least good short-term result can be expected with the percutaneous techniques (Figs. 86.1A to F).

Combined Stabilization

Combined anterior-posterior stabilization may be indicated in cases with severe destruction of the vertebral body or insufficient spinal canal clearance after posterior decompression.³¹ In comparison to isolated posterior stabilization, additional anterior stabilization improves biomechanical stability and leads to less loss of correction in the postoperative course.^{32,33} Since bone harvesting from the iliac crest carries a significant risk of morbidity, we recommend the use of titanium mesh cages or expandable titanium cages. Care should be taken to adjust the angulation of the endplates according to the local degree of lordosis (Figs. 86.2A to E). Otherwise, implant subsidence may occur. The additional use of an anterior plate can

further increase the stability and enhance bony fusion, but does neither affect cages subsidence, nor clinical outcome.³⁴

Today, minimally invasive anterior approaches are technically feasible, safe, and effective.³⁵ The anterior retroperitoneal approach to the lower lumbar spine can either be performed from the front or from the side. From the authors' experience, L4 and L5 should be addressed via an anterior (pararectal) retroperitoneal approach. At the levels L4 and L5, the main vessels have to be mobilized before proper corpectomy and fusion can be performed (Fig. 86.2C). At the level L3, both anterior and lateral retroperitoneal approaches are possible. In patients with bulky psoas muscles, the lateral approach carries the risk of damaging the lumbar plexus.

Complications

With an overall complication rate of approximately 9% in large series, surgery for thoracolumbar trauma has shown to be relatively safe.³³ Typical complications are infections, loss of correction, and implant failure, respectively. The rate of reported revision surgery due to complications is 2.8%.³³ Available studies concerning the surgical treatment of lower lumbar spinal fractures only include low numbers of patients. Therefore, limited information concerning complications can be obtained from them. Implant failure, especially in posterior surgery without anterior support, reflects the typical complication in up to 27%.¹⁴ Infections are reported in up to 18%.^{12,14} Typical reasons for revision surgery were hardware complications or progressive kyphosis.⁵

The anterior minimally invasive access carries an overall complication rate of 12.5%. Typical complications are dural tears (2.5%), intercostal neuralgia (2.5%), deep vein thrombosis (2.5%), pleural effusion (1.3%), wound infection (1.3%), hardware failure (1.3%), and hemothorax (1.3%), respectively.³⁶

POSTOPERATIVE CARE

Postoperative rehabilitation should start immediately after surgery. Patients can be mobilized without a brace but should not lift heavy weights for up to 3 months. Standing X-rays should be obtained after 1, 4, 12, and 48 weeks, respectively. Accompanying physiotherapy can reduce postoperative discomfort and ease occupational rehabilitation. Strengthening of both, abdominal and lumbar muscles, should be conducted. Occupational therapy is recommendable, especially in elderly patients.

Figs. 86.1A to F: A 69-year-old male patient with osteoporosis (T-score -3.64) and increasing pain after he collapsed 5 months ago. On admission, heavy back pain (VAS 9) and neurogenic claudication. Complete burst fracture of L3 (A3.3 AO-Magerl). Conservative treatment attempt failed. Posterior percutaneous PMMA-augmented stabilization from L2 to L4 and minimally invasive interlaminar spinal decompression at L3/4. At 6-month follow-up, moderate back pain (VAS 3) and unlimited walking distance.

PROGNOSIS

Good to excellent outcome can be expected in 66–90% of patients, regardless of the type of treatment.^{5,11} However,

only one-third of patients report no pain at all after 2 years, and only 14% report unrestricted back function.³³ The return to work rate is between 64% and 100% depending on the neurological status.^{5,11,16} Conservative treatment

Figs. 86.2A to E: A 22-year-old polytraumatized male patient with complete burst fracture of L5 (A3.3 AO-Magerl) and neurological deficit (ASIA B). Immediate posterior bisegmental stabilization and fusion (L4–S1) including laminectomy of L5. Staged anterior minimally invasive retroperitoneal corpectomy L5 and vertebral body replacement with expandable cage. Six-month follow-up with improvement in neurological deficit (ASIA C).

seems to carry no risk for neurological deterioration, regardless of the type of fractures.^{5,10-12} However, improvement in neurological deficits after surgery is reported in 42–87%.^{5,13} Anterior decompression may improve neurological deficits in selected cases, too.¹⁰ Surgery leads to significantly better radiological results regarding the final kyphotic deformity and the loss of vertebral height.^{5,10,16,33} But no study could prove any correlation between radiological and clinical outcome so far. About half of the patients reported localized pain after posterior stabilization and 42% reported localized pain after anterior stabilization.³³

KEY POINTS

- Lower lumbar injuries between L3 and L5 only account for a small percentage of thoracolumbar fractures.

- Traumatic axial compression forces produce uniform compression of the vertebral body rather than kyphotic deformity.
- Conservative treatment (bracing) can be chosen in stable fractures with posterior ligamentous continuity.
- Neurological deficits and highly unstable fractures are indications for surgical stabilization.
- Short posterior stabilization with transpedicular screws is sufficient in the vast majority of cases.
- The majority of patients will achieve good to excellent outcome but residual back pain is common.

INTRODUCTION

Optimal management of sacral fractures is multifactorial with emphasis on fracture classification or morphology, neurologic status, general medical condition, and local soft tissue environment (skin). Given the relative paucity of sacral fractures and complex management, the literature and subsequent treatment recommendations are primarily based on retrospective studies. Surgical treatment goals for unstable sacral fractures include reduction and stabilization of pelvic ring and/or spinopelvic integrity while preventing deterioration of neurologic deficits, and allowing early mobilization, rehabilitation, and recovery.

EPIDEMIOLOGY

Sacral fractures are typically high-energy traumatic injuries, which have classically been characterized as pelvic more than spinal fractures [anteroposterior compression (APC), lateral compression (LC), vertical shear, or combined pelvic mechanisms]. About 57% sacral fractures result from motor vehicle crashes, 18% from motor vehicles striking pedestrians, 9% from motorcycle accidents, 9% from falls from a height, and 4% from crush injuries.^{1,2} Sacral fractures occur in 10–45% of all pelvic fractures^{1,3–7}

and <2–5% of sacral fractures occur as isolated injuries.^{1,8,9} The latter typically results from a direct blow or fall onto the sacrum. Among types of sacral fractures, 5–16% are transverse and carry a high frequency of neurologic injury.^{5,6}

ANATOMY

The sacrum serves as the anchor of the pelvic ring attaching to bilateral pelvic arches (ilium, ischium, and pubis) via stout anterior and posterior sacroiliac ligaments. It also connects the mobile lumbar spine to the pelvic ring. Sacral injuries understandably cause not only pelvic ring but also spinopelvic instability, which may result in severe neurologic deficits.^{10–13} Neurologic injuries caused by sacral fractures range from incomplete mono radiculopathies (root palsies) to complete cauda equine syndrome. Additionally, ventral rami of the S2 through S5 roots contribute to the prevertebral and presacral parasympathetic plexus and nerves that regulate sexual function, bladder, and rectal function. Surgical anatomy mandates understanding the location of the L5 nerve roots that lie on the anterosuperior surface of the S1 vertebral body and ala. These roots are susceptible to a neurapraxis stretch injury during open book APC pelvic injuries. They are also the most likely root to be injured with inadvertent placement of sacroiliac

screw fixation. Lastly, the posterior rami of the sacral roots consist of small sensory fibers, with contributions to the cluneal nerves, which are susceptible to injury during harvesting of posterior iliac bone graft procedures.

ASSESSMENT OF SACRAL FRACTURE

Sacral fractures are often associated with other concomitant high-energy injuries. Multiply-injured polytrauma patients are often obtunded, comatose with up to 20% of these patients either unconscious or intubated prior to appropriate orthopedic or neurologic consultations.¹⁴ Hence, proper complete history, physical and neurologic examinations are difficult. Standard advanced trauma life support principles are mandatory as sacral fractures are frequently overlooked at initial presentation in 24–70% of cases.¹⁵

- When pelvic or sacral fractures are suspected, identification of the following must occur: Presence of life-

threatening hemorrhage from iliac vessels, anterior perisacral venous plexus, or superior gluteal artery. These are often associated with APC (open book pelvic fractures) type injuries that require emergent volume reduction in the pelvic ring with a sheet around the trochanters, pneumatic compression devices, or, rarely, pelvic clamps until placement of an anterior pelvic external fixator can be applied (Figs. 87.1A to C). Volume replacement and subsequent arterial embolization must be arranged concomitantly.

- Presence of extensive lumbosacral fascial degloving injury (Morel-Lavallee syndrome) that substantially affects strategy of surgical treatment.
- Presence of concomitant thoracolumbar fractures.
- Presence of neurologic injury. Neurologic examination includes motor and sensory function, reflexes, and elicitation of reflexes including the perianal wink, the bulbocavernosus, and the cremasteric reflexes are

Figs. 87.1A to C: Anteroposterior pelvic radiograph (A) demonstrating anterior widening between the two pubic arches. The patient had an unstable anteroposterior compression injury with the anterior pubic rami splaying and posterior sacral widening with horizontal instability (B) that required immediate anterior external fixator placement and subsequent posterior open reduction and tension-band plating of the sacral fracture (C).

recommended. Light touch and pinprick sensation along the perianal concentric dermatomes of S2 through S5.

- Presence of pelvic ring and spinopelvic instability.
- Presence of injuries to the genitourinary system (urethral, bladder) secondary to displaced fracture fragment.

RADIOGRAPHICAL EVALUATION

Two-view radiographic evaluation using only a standard anteroposterior (AP) and cross-table lateral X-rays of the pelvis often do not adequately diagnose sacral fractures. Pelvic inlet and outlet radiographs are recommended to improve visualization of the sacrum. Associated signs of sacral fractures on plain X-rays are L4 or L5 transverse process fractures, anterior pelvic ring disruptions, and a “stepladder” sign.¹⁶

Computed tomography (CT) is recommended for diagnosis and determines fracture type. Additionally, sagittal and coronal reconstruction images with or without 3D reconstructions should be obtained for better visualization of the fracture and are essential to best categorize the fractures.

Magnetic resonance imaging (MRI) is not only superior in evaluating the neurologic and soft tissue (ligamentous) structures but also significantly helps in determining sacral stress fractures, insufficiency fractures.

CLASSIFICATION

Sacral fractures were often included into the classification of pelvic ring fractures including the Letournel, Tile, and AO-ASIF classification systems that identify the force imparted on the pelvis as well as the resultant instability (vertical or horizontal). Several additional “spine based” classifications have been developed for sacral fractures.

Denis Classification¹

Denis classification system of sacral fractures divides the sacrum into three zones in relation with the position of neural foramina and spinal canal.

Zone I: Fracture line is lateral to the neural foramina. It is the most common pattern (50% of the fractures in the series of Denis et al.), which resulted in sciatic nerve or L5 nerve root injury in 5.9% of cases.

Zone II: Fracture line is through foramina. It is the second most common pattern (34% of the fractures in the series),

which resulted in L5, S1, or S2 injury in 28.4% of cases. Zone II fractures with a shear component have increased risk of neurologic deficits.

Zone III: Fracture lines involve the spinal canal. It is the least frequently encountered fracture pattern (16% of the fractures in the series). Neurologic deficit occurred in 56.7% of patients. Transverse fractures involving the S1-S3 segments tend to have a higher prevalence of bladder dysfunction than those at S4 and below. Among neurologic injuries, bowel and bladder control or sexual function was impaired in 76% patients. Since bilateral zone I or II injuries are extremely rare, closer inspection for zone III injury and an obscure transverse fracture line should be performed using CT coronal images.

Subclassification of Denis Zone III Fracture

The transverse fracture in Denis zone III was further classified in to three types by Roy-Camille.¹⁷

Type 1: Simple flexion deformity of the sacrum with minimal to no translation.

Type 2: Incomplete anterior sacral translation with kyphosis.

Type 3: Complete translation with complete sacral displacement.

Strange-Vognsen and Lebech further modified Denis zone III fracture by adding type 4.¹⁸

Type 4: Segmental comminution of the S1 vertebral body caused by axial loading.

Isler System¹⁹

Isler system classify sacral fracture based on the location of the major vertical fracture line relative to L5-S1 facet, which predicts the potential of lumbosacral subluxation or complete lumbopelvic dissociation.

Type A: Fracture through the sacrum and located lateral to L5/S1 facet. This type of fracture will not cause lumbosacral instability, but may have some negative impact on pelvic ring stability.

Type B: Fracture through the sacrum and run through the L5-S1 facet. The fracture can be differentiated as extra-articular fractures of the lumbosacral junction and articular dislocation with displacement of the facet.

Type C: Fractures through medial to the facet crossing into the neural arch. These fractures may lead to significant instability and can lead to lumbosacral dissociation when occurred bilaterally.

Descriptive Classification

U-shaped fracture is first described by Roy-Camille in 1985.¹⁷ Additional morphologic variations in this fracture pattern have been described as “H,” “T,” and “lambda” patterns when associated with other pelvic ring disruptions.

U-shaped fractures were further classified into four types by sagittal displacements by subclassification of Denis zone III fracture.^{17,18} U-shaped sacral fractures usually result from a significant amount of axial load to the spine by which pivoting of the sacrum occur. The most common

mechanism of injury was suicidal jump,²⁰ followed by fall from height.²¹ These two injury patterns are responsible for the majority (67.2%) of all published cases. The horizontal fracture usually occurs between S1 and S2 and causes dissociation of the spinal column and the pelvic ring. The rostral part of the sacrum stays attached to the lumbar spine with the caudal part attached to the pelvic ring resulting in the aptly named spinopelvic dissociation. This type of fracture has a wide ranging potential of neurologic injuries from incomplete radiculopathy to complete cauda equina syndrome and ruptured nerve roots.^{1,6,9,22-24} Amongst patients with spinopelvic dissociations, neurologic injury was noted in 94.3%.²⁵

SACRAL INSUFFICIENCY FRACTURES

Sacral insufficiency fractures were first described by Lourie in 1982.²⁶ Sacral insufficiency fractures are estimated to occur in 1–5% of women aged above 55 years²⁷⁻²⁹ who are associated with postmenopausal osteoporosis.³⁰⁻³⁴ Insufficiency fractures are a subtype of stress fracture that results from normal stress applied to abnormal bone that has lost its elastic resistance. Sacral insufficiency fractures can occasionally be confused with metastatic disease, both clinically and on imaging studies.³⁵ The most common physical signs are low back or groin tenderness and restricted hip movement^{36,37} Neurologic deficit is rare. Usually, patients present with no history of trauma or a history of low-impact trauma.

The diagnosis of sacral insufficiency fracture is usually difficult by X-rays.³⁸ Bone scintigraphy and MRI are the most sensitive screening investigation. Magnetic resonance imaging can pick up signal from bone marrow edema that results from fracture inflammatory and reparation processes. T1-weighted images demonstrate a low signal intensity, while T2-weighted images demonstrate high signal intensity. T2-weighted short tau inversion recovery images and T2-weighted images with fat suppression are particularly sensitive to demonstrate fractures.³⁹

Bone scintigraphy with technetium-99 m medronate methylene diphosphonate is a sensitive technique for detecting sacral insufficiency fracture.^{32,37} A classic “H” pattern,⁴⁰ is considered to be diagnostic. However, the “H” pattern requires bilateral involvement and a horizontal fracture component to the sacral body that is not always present.

Conservative treatment is standard for treating sacral insufficiency fracture and consists of bed rest, restricted weight bearing, and analgesics for pain relief.^{37,41} Symptoms resolve in most patients by 12 months but can vary between 6 and 15 months.^{36,37,41,42} In fact, half of patients with pelvic insufficiency fractures will not return to their prior functional level, and there is a reported 14.3% overall mortality.⁴³ More recently, minimally invasive cement augmentation techniques similar to vertebroplasty have been advocated by interventionalists (sacroplasty) as an alternative to conservative therapy.⁴⁴⁻⁴⁸

■ NONOPERATIVE TREATMENT

Historically, indications for nonoperative management included nearly all sacral fracture patterns as implants were inadequate for reconstruction of these highly complex injury patterns. Contraindications to nonoperative care are an incomplete neurologic deficit with objective evidence of neural compression, and extensive disruption of the posterior lumbosacral ligaments. Nonoperative care consists of prolonged bed rest in skeletal traction, bed rest in a brace or cast with a unilateral or bilateral hip spica, brace immobilization (with a thoracolumbar spinal orthosis with a hip spica) with protected weight-bearing, or, ideally, early mobilization with protected weight-bearing. Typically, 2–4 months are required for healing a posterior pelvic ring fracture. Repeat imaging studies should be performed to verify that fracture healing is proceeding with satisfactory alignment (especially prior to anterior external fixator removal). Prolonged recumbency has increased risks of

thromboembolism, pulmonary complications, and skin breakdown. In terms of neurologic recovery, controversy still exists whether clinical results of surgical intervention are superior to conservative treatment.⁴⁹

■ SURGICAL TREATMENT

The goals of surgical treatment are anatomic reduction and stabilization of the fracture(s) with restoration of lumbosacral alignment in order to improve and/or prevent neurologic deficit, residual pain, and to enable early mobilization.^{50,51}

In patients with zone I and zone II fractures, surgical delays >5 days after injury were associated with less anatomic closed reductions.⁵² Delays >2 weeks in patients with neurologic compromise resulted in poorer outcomes.¹ Although surgical treatment should be considered as early as possible, the timing should be decided based on the purpose of treatment, the patient's general medical status, and the invasiveness of the intended surgical procedure. Early aggressive surgery in under-resuscitated patients can lead to undesirable surgical outcomes including excessive intraoperative blood loss, soft-tissue breakdown, and infection.

Sacral fracture surgical management options are best classified into treatment of unstable pelvic ring injuries and treatment of spinopelvic instability.

■ TREATMENT OF UNSTABLE PELVIC RING INJURY

For sacral fractures associated with substantial unstable pelvic injuries [APC II/III (anterior symphyseal widening >4cm), LCII/III fractures (horizontal instability associated with a combination of pubic/iliac/sacral fractures), and nondisplaced unilateral vertical shear fractures], the goal is to reduce pelvic volume to minimize additional blood loss by reduction in a displaced pelvic ring fracture including temporary skeletal traction, application of an anterior external fixator, placement of a pelvic clamp, or use of a wrap-around sheet. Additionally, radiologic intervention techniques such as angiographic embolization of bleeding vessels should be considered (*see Figs. 87.1A to C*).

During surgery, the anterior fixation should be considered prior to posterior lumbosacral procedure.² Usually, the anterior pelvic ring injury can be realigned and stabilized by anterior plate fixation, external fixation, or the use of retrograde pubic screws. This can partially stabilize the pelvic ring during a posterior procedure with prone posi-

Figs. 87.2A to C: Lateral sacral (A), inlet (B), and outlet (C) pelvic radiographs demonstrate ideal safe placement of S1 and S2 ilio-sacral screws.

tion and can enhance the reduction in the posterior part of the pelvic ring.

Denis type I fractures, nondisplaced vertical shear fractures, and other displaced, unstable (widened not compressed) sacral fractures not associated with neurologic impairment that do not appear to have closed down with anterior pelvic ring restoration with external fixator or anterior pelvic plating should be considered for posterior pelvic ring fixation. Use of traditional open reduction with posterior tension band plating techniques with fixation into bilateral posterior ilium is appropriate in patients who do not appear closed reduced completely pre- or intraoperatively (*see* Fig. 87.1C). However, percutaneous transiliac iliosacral screw fixation predominates now. Full bowel prep is helpful but not always mandatory, and avoidance of nitrous anesthesia is mandatory so bowel loops do not obstruct fluoroscopic guidance. It requires a combination

use of the lateral sacral view (to determine starting point and avoid the L5 root safely), inlet (to determine anteroposterior placement not in the canal), and outlet views (to avoid the neuroforamina) for safe screw placement.²⁰ A single 7.3 mm cannulated S1 screw, 2 S1 screws, or screws in S1 or S2 are possible depending on fixation needed (Figs. 87.2A to C). Fully threaded screws should be used in Denis II fractures to not further compress the neuroforamina and cause iatrogenic root injury. Partially threaded screws are indicated for sacroiliac joint widening or mildly displaced zone I fractures needing compression. Lastly, displaced anterior sacroiliac dislocations or fracture-dislocations in which the fracture lines do not exit posteriorly are best approached with an anterior ilioinguinal retroperitoneal approach to open reduce then placement of either a stout anterior sacroiliac plating that straddles the SI joint or posterior iliosacral fixation.

TREATMENT OF SPINOPELVIC INSTABILITY

While rare, spinopelvic instability can be a devastating lesion clinically and the lumbar spine dissociates from the sacropelvis typically via slipping into a position anterior to the sacrum. The lesion can occur with bilateral dislocations of the sacroiliac or L5-S1 facet joints, or trans-sacral fractures. Traumatic spinopelvic dissociations or U-shaped sacral fractures are characterized by a transverse sacral fracture in conjunction with bilateral sacral fracture-dislocations, resulting in mechanical dissociation of the upper sacrum and spine from the pelvis. The term of traumatic spinopelvic dissociation was proposed by Bents et al. to distinguish this injury pattern from lumbosacral fracture-dislocations or bilateral sacroiliac joint dislocations.^{10,13} For U-shaped fractures, spinopelvic fixation with L4 and/or L5 pedicle screws, iliac fixation (1 or 2 screws bilaterally), and screws (or triangular osteosynthesis) can provide optimum reconstruction and stability²⁵ (Figs. 87.3A to F). Iliosacral screw fixation as percutaneous osteosynthesis was performed in 31.7% of the U-shaped fractures in which the screws were either inserted unilaterally, bilaterally, or trans-sacally.²⁵ Failure to recognize the vertical instability associated with these fractures can often fail traditional pelvic reduction and fixation techniques alone (Figs. 87.4A to H).

FIXATION TECHNIQUE

Posterior stabilization techniques include percutaneous sacroiliac screw fixation, bilateral sacroiliac screw fixation

with posterior tension-band plate fixation, posterior alar plate fixation, and lumbopelvic segmental fixation. For decision making of the surgical strategy, skin condition including the presence of a Morel-Lavallee lesion can also be evaluated.

Triangular Osteosynthesis Technique

Triangular osteosynthesis technique combines the vertical component (lumbopelvic distraction osteosynthesis) with transverse fixation (iliosacral screw or transiliac/trans-sacral plate) that can allow early postoperative mobilization with full weight bearing.⁵³ In a cadaveric study comparing the biomechanical stability for vertical transforaminal fractures, the triangular osteosynthesis provides significantly greater stability than sacroiliac screws in vitro cyclical loading conditions.⁵³ In terms of complications, wound infections and pain due to prominent of spinal implants are comparatively common in patients with triangular osteosynthesis. In the systematic review, 3 out of 6 patients (50%) with triangular osteosynthesis and 2 out of 19 (10.5%) in the largest series of spinopelvic fixation needed removal of metalwork.^{11,12}

Lumbar Pedicle Screw and Iliac Screw

The construct consists of lumbar pedicle screws and iliac screws connected by longitudinal rods and transverse connectors to facilitate fracture reduction and stabilization. This construct also allows patient early ambulation without a brace. Complete decompression of neural tissues can be done using this construct.

Figs. 87.3A and B

Figs. 87.3C to F

Figs. 87.3A to F: Initial trauma bay anteroposterior (AP) pelvis radiograph (A) demonstrating the H-type sacral fracture and right anterior pelvic ring fracture. Coronal (B) and axial (C) pelvic computed tomography images demonstrate the severe comminuted, unstable sacral fracture with three-dimensional coronal reconstruction (D). Postoperative AP pelvis (E) and lateral lumbosacral spine radiographs (F) demonstrate L4-S1 spinopelvic instrumentation (Synthes Pangea, West Chester, PA), right iliosacral screw fixation with a Synthes partially threaded 6.5 mm cannulated screw, and open reduction internal fixation (ORIF) R anterior pelvic ring fracture with a Synthes 3.5 mm pelvic reconstruction plate.

Sacroiliac Screw

Sacroiliac screws, originally intended for sacroiliac joint injuries, are useful for treating vertical sacral fractures and sacral disruption.⁵⁴ The screws can be placed percutaneously under fluoroscopy with the patient in either the prone or supine position. Placement of screws is highly dependent on fluoroscopic imaging. The safety of these screws has been established in multiple clinical trials,^{28,55,56} and injury to neurovascular or gastrointestinal structures has been described as a rare complication. Potential indications for percutaneous placement of sacroiliac screws include a Denis zone I, II, or III sacral fracture, which can

be adequately reduced in a closed fashion. Denis zone III, Roy-Camille type 2, 3, or 4 injuries are less amenable to this form of fixation as a stand-alone device because of the inability to reduce these injuries by closed fashion. In zone II, fractures with segmental comminution are susceptible to overcompression and secondary foraminal entrapment when an iliosacral compression screw is used. Such injuries may be considered for fixation with two static sacroiliac screws or for iliolumbar segmental fixation.²

Nork et al.⁵⁵ reported successful results of percutaneous sacroiliac screw fixation in 13 patients with a Denis zone III, Roy-Camille subtype 1 or 2 fracture, and no substantial neurologic deficit. No deterioration of the sacral kyphosis

Figs. 87.4A to F

Figs. 87.4G and H

Figs. 87.4A to H: Anteroposterior pelvis radiograph (A) and computed tomography (CT) axial and coronal reconstruction images demonstrate severe left-sided pelvic fracture, combined vertical shear-LC [rotationally and vertically unstable Tile (B and C)] after initial fixation (D) and failure (E) of fixation with anterior ring open reduction internal fixation and closed reduction percutaneous posterior pelvic ring pinning. After removal of hardware, L4-Ilium spinopelvic fixation with intraoperative reduction was accomplished with posterior segmental instrumentation (Synthes Pangea, West Chester, PA) (F). Note the cranial screws require additional cross connectors, while the caudal screws hook directly to the rods. Postoperative CT (G and H) demonstrates screws in the ilium and supra sciatic notch column extending toward the anterior inferior iliac spine (AIIS).

angle was found despite the fact that the post-traumatic deformity was stabilized without aggressive attempts of reduction. The authors recommended insertion of bilateral midline-crossing sacroiliac screws when the technique is used to treat a zone III “H” or “U” fracture configuration.

DECOMPRESSION SURGERY

In the presence of satisfactory skeletal stabilization but persistent neuroforaminal or spinal canal compromise, a focal limited decompression may be performed with use of a limited midline exposure. From a neurophysiologic standpoint, decompression of compromised neural elements is preferably performed early, within the first 24–72 hours following injury, because of epineural fibrosis and increased scarring of the central canal and foramina. However, given an overall rate of neurologic improvement of approximately 80% regardless of treatment, the indications for and timing of surgical decompression in patients with neurologic injuries are somewhat controversial.^{6,57,58}

INTRODUCTION

The sacroiliac joint (SIJ) is a highly specialized and heterogeneous synovial joint that connects the axial skeleton to the lower extremities, allowing the transfer and dissipation of forces between the two body regions. As a result, the joint has developed a unique bony anatomy with abundant ligamentous connections conferring this necessary stability. The minimal, but essential, physiologic motion that occurs in the SI is rarely a source of pain, but alterations to the joint as a result of trauma, pregnancy, or degenerative disease can result in abnormal motion and pain.

The SIJ along with its associated capsular and ligamentous structures are estimated to be the causative agent in approximately 15–20% of patients who present with axial low back and buttock pain.¹ The role of the SIJ in back pain has certainly undergone a great shift. At the turn of the 20th century, the SIJ was thought to be the principal cause of back pain and sciatica; however, the work of Mixter and Barr shifted focus to the herniated disc and with the advent of magnetic resonance imaging (MRI), the SIJ became an afterthought for most spine specialists, and perhaps an underappreciated cause of back pain. Nonetheless, the SIJ can be responsible for the symptoms in a subset of patients with low back and buttock pain as well as patients with persistent or new back pain after lumbar fusion, and a

thorough knowledge of the diagnosis and treatment of the dysfunctional SIJ can improve the care of these patients and avoid interventions aimed at treating discogenic or zygapophyseal joint pain in this population.

ANATOMY

The SIJ is a highly specialized diarthrodial synovial joint connecting the sacrum to the two ilia, critical for the transfer of loads between the spine and lower extremities. The sacrum is composed of five fused sacral vertebra, and the SIJ is typically formed between S1–S3 and the ilium.² The surface anatomy of the joint has been shown to be highly variable, but in general, the sacral portion is predominantly concave and the iliac portion is convex.³ This matching interdigitating anatomy provides inherent stability of the SIJ construct, as these surfaces have the highest coefficient of friction of any diarthrodial joint.^{4,5}

Further stability of the SIJ is provided by the multitude of primary and accessory SI ligaments that span the joint, including the ventral, dorsal, and interosseous ligaments. The anterior sacroiliac ligament is the thickened anterior capsule composed of dense connective tissue that extends between the ventral surfaces of the sacrum and ilium. The ventral SIJ capsule, as compared to other SIJ ligaments, is relatively thin, and Fortin et al. demonstrated the dispersion of contrast ventrally out of the SIJ in approximately

60% of patients undergoing intra-articular injections, indicating that these connections are not nearly as robust as their dorsal counterparts.⁶ In fact, only the anterior portion of the joint is truly synovial in nature and the dorsal aspect is composed of a network of interosseous SI ligaments.⁷ These interosseous ligaments have the largest volume of all the SIJ ligaments and in turn supply the greatest contribution to multidirectional stability.⁸ There are numerous dorsal accessory SIJ stabilizers, including the iliolumbar, sacrospinous, and sacrotuberous ligaments. Vrahas et al. later confirmed the importance of the interosseous and posterior ligaments and demonstrated the minimal role of the anterior SI ligaments on joint mobility.⁹

The joint surface of the SIJ is equally unique. The cartilage on the sacral side reaches a thickness of approximately 4 mm, while that on the ilium side does not exceed 1–2 mm at maturity, nearly three times thinner.^{7,10} Not only does the quantity of cartilage differ, but the quality of cartilage on the two sides of the joint is also quite different. Cartilage on the sacral side appears histologically similar to typical hyaline cartilage. Cartilage on the ilium side resembles fibrocartilage, and was only recently determined to be a more specialized variant of hyaline cartilage.¹¹
